In an effort to locate the regions involved in extracting texture gradients Shikata E. *et al.* (2001) investigated 3D orientation discrimination, but in this case also 2D controls were lacking, perhaps because the 2D shape selectivity of parietal cortex (Denys, K. *et al.*, 2004) had not been appreciated well enough. The extent to which these 2D cues also contributed to the change in perspective effects documented by Welchman A. E. *et al.* (2005) in hMT/V5 and LOC is unclear.

2.15.6 Conclusions

The veil that has long covered the extraction of 3D shape from the retinal inputs has only begun to be lifted. An important step in this direction is the recognition that 3D shape and depth are different perceptual entities. With the availability of monkey fMRI the pace of progress should accelerate (Durand, J. B. *et al.*, 2007).

The extraction of 3D SFM exemplifies the strength of the triadic approach in which the same perceptual/cognitive process is probed by single-cell recording, and by fMRI in awake monkeys and humans. Indeed all three experimental strategies underscore the contribution of MT/V5 and its human homolog to the 3D SFM, even though the stimuli used in the three approaches were not identical. Furthermore, even if the homology is generally accepted at the level of the MT/V5 complex, the detailed homology between MT/V5 and each of its satellites in two species has still to be worked out (Huk, A. C. *et al.*, 2002; Nelissen, K. *et al.*, 2006). This approach may document further species differences in addition to that documented in the primate IPS (Vanduffel, W. *et al.*, 2002). Although both humans and monkeys perceive 3D structure form motion similarly (Siegel, R. M. and Andersen, R. A., 1990), human IPS processes 3D SFM much more extensively than its monkey counterpart. We have proposed that this is due to the much wider use of tools in humans than in monkeys. This view has received support recently from the study of Stout D. and Chaminade T. (2007).

The neuronal mechanisms unraveled so far clearly indicate that 3D shape is not represented as a 3D map, underscoring the distinction between depth and 3D shape. Rather the primate brain has evolved mechanisms to extract the linear- and second-order gradients in speed and disparity from the retinal images. The direct encoding of these first- and second-order derivatives is one of the main conclusions that can be derived from the studies performed so far. In the case of speed gradients in MT/V5 the encoding of gradients involves the surround. Whether this will turn out to be a general mechanism or not remains an open question. Indeed the coding by speed is relatively coarse (Orban, G. A., 1997) and a mechanism based solely in the ERF cannot capture enough of the speed variation to be sensitive. Other neural encoding mechanisms such as those of disparity are finer (Poggio, G. F. and Fischer, B., 1977) and hence a purely excitatory mechanism might suffice.

A third conclusion that can be derived from the data available is that 3D shape is processed both by the ventral and dorsal stream, in agreement with the double behavioral use of 3D shape in identification/categorization and in guidance of action, in particular grasping. How different these dorsal and ventral representations of 3D shape are remains an open question and will require a direct comparison of neuronal populations in both streams.

Another question which has hitherto received insufficient attention is the distinction between the processing of the 3D shape of objects and the 3D layout of the environment. In the studies performed so far widely different stimulus sizes have been used. The interaction between the extraction of 3D structure and size will have to be studied much more systematically to dissociate these two aspects of 3D structure.

Acknowledgments

The work described in parts of this chapter was supported by GOA 2000/11, GOA 2005/18, IUAP P5/04, EU grants Insight2 and Insight2+, FWO G0151.04. The author is indebted to Dr. J. T. Todd and Dr. S. Raiguel for comments on an earlier draft and Dr. G. DeAngelis for commenting on an earlier version of the draft and providing Figure 6.

2.16.1 What is Visual Search?

The world presents the visual system with more information than it can process at any one time. In response, the visual system and other sensory systems have selective processes that restrict full analysis to a subset of the available input. If an observer wants to deploy visual processing resources to some item that is not the current object of attention, the observer will need to search for that item. Even when the observer has no particular top-down goal, the limited resources of the visual system must be deployed in some manner in response to the current stimulus situation. Research on visual search examines the ways in which visual system uses attentional mechanisms to find something in a world filled with other things.

Attention is a broad term that covers a variety of different selective operations in vision and elsewhere. Two specific examples can illustrate the range of uses of attention in visual search.

2.16.1.1 Detection Under Conditions of Location Uncertainty

Imagine a clock face arrangement of 12 disks of visual noise. You are asked to find a signal (e.g., an oriented blob) embedded in the noise. The whole display is presented very briefly. If you are told that the signal, if present, will be at the 7 o'clock position, you will be better at detecting that signal than if you are uncertain about the location. This will be true even though the visual stimulus is identical in the two cases. Apparently, the ability to direct attention to a subset of the stimuli changes the detectability of the target (Palmer, J. *et al.*, 2000).

2.16.1.2 The Binding Problem and Limits on Object Recognition

In most cases, the visual stimuli of interest are more complex than simple signals in noise. Often they are

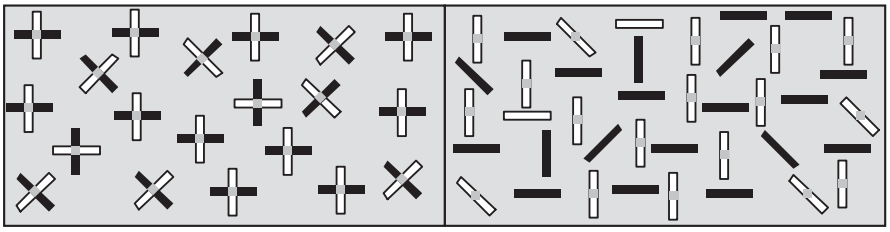

Figure 1 Search for the black vertical lines is harder on the left than on the right.

objects needing to be recognized. As a general rule, attention needs to select an object before that object can be identified. Attention is required because most objects have multiple attributes (e.g., the colors, shapes, and orientations of several parts and the relationship between those parts). In the absence of attention, those attributes cannot be bound together in a manner that permits unambiguous identification. This is known as the binding problem (Treisman, A., 1996; von der Malsburg, C., 1981). Figure 1 provides a demonstration.

It is relatively hard to find the plus with black vertical and white horizontal arms on the left (there are two of them) because there are other items that are black and white and vertical and horizontal in the figure. Without attention, the correct binding of color to orientation is not available. It is easier to find either black vertical or white horizontal on the right of the figure because the black vertical items are the only items with the properties, black and vertical. It would be even easier if the target was the only black or the only vertical item (see below). Figure 1 may also illustrate this point in another way. Look at the right panel of the figure and then return to this paragraph. Did you see a white bar, tilted to the right? If you are sure you did, you may have experienced an illusory conjunction of features (see Treisman, A., 1996). There are white objects and right tilted objects, but no white objects tilted to the right. Illusory conjunctions can be described as binding errors, perhaps reflecting the fact that color and orientation (in this example) are processed in different parts of the visual system and need to be bound to a single object, one attended object at a time.

2.16.2 How Do We Study Visual Search?

The choice of methods with which to study visual search depends on the question under study and the stimulus used. Searches with large detailed images require eye movements, as do most real-world searches. Measurements of those eye movements can give useful information about the progress of the search (Zelinsky, G. J. and Sheinberg, D. L., 1997). Voluntary, saccadic eye movements occur at a rate of about 3–4 Hz. Covert attentional deployments can be separated from the point of fixation and can occur at a faster rate. Many visual search tasks use stimuli large enough to render eye movements unnecessary or they present stimuli for a period brief enough to render voluntary eye movements impossible. Under these circumstances, the primary measures of search performance are derived from reaction time (RT) data and/or accuracy data.

2.16.2.1 Real Time Methods

In typical RT studies, observers search for a target item among a variable number of distractor items under the instruction to respond as quickly and accurately as possible. The primary interest is in the relationship of RT to set size, the number of items in the display. The slope of the RT × set size function is a measure of search efficiency, the rate with which items can be processed. In a search for a target defined by a single basic feature (e.g., a red target among green distractors), slope will be near zero, as if all items are processed in a single step. If no basic feature information distinguishes a simple target from distractors and if the items are large enough to be resolved without requiring eye movements, search slopes will typically fall in the range of 20–40 μs per item on trials when the target is present and a bit more than twice that when the target is absent. Going from that slope to an estimate of items processed per second requires assumptions about, for example, whether search samples the display with or without replacement (see below) or whether we have the attentional capacity to attend to more than one item at a time (Cavanagh, P. and Alvarez, G. A., 2005). Search slopes can be much steeper if items are hard to identify (e.g., a random complex target shape

among similar distractor shapes). If each item must be fixated, slopes will reflect the slow rate of eye movements (3–4 s^{-1}).

2.16.2.2 Accuracy Methods

In RT tasks, stimuli are typically visible until response, and errors are typically held to 5–10%. False alarm errors are very rare. Accuracy methods typically use brief presentations and/or degraded/masked stimuli in order to force observers to respond on the basis of incomplete information. This creates patterns of errors that are amenable to analysis by various decision theory methods. RT and accuracy methods often produce converging results but the different stimulus conditions sometimes lead to different conclusions about underlying mechanisms of search. For example, effects of reentrant feedback will be hard see with brief, masked stimuli (Di Lollo, V. *et al*., 2000).

2.16.2.3 Neurophysiological, Lesion and Microstimulation Studies of the Neural Mechanisms that Mediate Visual Search

Electrophysiological studies in humans and nonhuman primates have helped characterize the neural mechanisms that mediate visual search. The N2pc component of the event-related potential (ERP) has been an effective measure of the temporal dynamics of attention. Positron emission tomography (PET) and functional magnetic resonance imaging (fMRI) have been used to identify a frontoparietal network of regions active in search. These studies are complemented by microstimulation studies in nonhuman primates that have implicated the frontal eye fields (FEF) in the allocation of spatial attention (Moore, T. and Fallah, M., 2001). Studies in nonhuman primates have found that selection of a target from among distracters is strongly impaired when extrastriate visual areas V4, TEO, and MT are lesioned (Schiller, P., 1993; De Weerd, P. *et al*., 1999). Single-unit recording studies have found that neurons in these and other visual cortical areas are more responsive to stimuli that appear at an attended location (for a review, see Reynolds, J. H. and Chelazzi, L., 2004). There is also evidence that these areas are modulated by nonspatial forms of attention. For example, Chelazzi L. *et al*. (1993) trained monkeys to perform a visual search task in which the target was presented and then, after a brief pause, a search array appeared. They found that, during the pause period, the baseline firing rate of neurons in area TEO was elevated whenever the monkey prepared to search for a target that contained the neuron's preferred features. Then, when the search array appeared, the response to the array was initially undifferentiated, but over time separated out, with higher firing rates observed on trials when the monkey was searching for the preferred stimulus. This elevated firing rate occurred in the absence of knowledge about where the target would appear in the array, so it illustrates a spatially nonselective, feature-selective signal that is posited by the guided search model. Evidence for feature-based attentional signals has also been found in areas V4 and MT. Feature-based attentional modulation has also been observed in human subjects using fMRI (reviewed in Reynolds, J. H. and Chelazzi, L., 2004). The view that has emerged from these studies is that the frontoparietal network that is active during search is the source of spatial and nonspatial descending control signals that modulate the responses of neurons in the visual cortices, causing them to enhance processing of visual targets while suppressing processing of irrelevant distracters.

2.16.3 What Determines the Efficiency of Visual Search

2.16.3.1 Feature Guidance

As noted above, some visual search tasks are highly efficient, with attention directed to the target item with little or no distraction from other items. A limited number of stimulus attributes seem to be able to guide attention to targets. These include obvious attributes such as color and size as well as less obvious attributes such as a variety of depth cues. Some important features of the stimulus (e.g., intersection type) fail to attract attention. Similarly, even though they are very interesting to the visual system, stimuli like faces and letters do not seem to guide attention (though this remains a contentious point). The set of guiding attributes probably numbers 12–18 (Wolfe, J. M. and Horowitz, T. S., 2004).

Even if a target is defined by a guiding feature, search will be efficient only if a variety of other conditions are met. Search efficiency declines as the similarity of targets and distractors increases. Thus, search for 0° (vertical) among 30° distractors is typically efficient while search for 0° among 10° is not. Search efficiency declines as the heterogeneity of the distractors increases. Thus, search for green among yellow is trivial. Search for green among yellow, red,

blue, etc. is less efficient. For purposes of guidance, attributes appear to be coarsely and, perhaps, categorically coded. For example, a target tilted 10° to the right of vertical will be easier to find among distractors tilted 50° to the left and 50° to the right of vertical than among distractors tilted 70° to the right and 30° to the left. In both cases, distractors are 40° and 60° different from the target but in the first case, the target is uniquely steep. It is not uniquely steep in the second case because the 30° items are also steep.

2.16.3.2 Other Factors

Targets can be identified by conjunctions of features. Thus, search can be very efficient for targets that are red and vertical among distractors that are red and horizontal or green and vertical. Most real world search items are conjunctively defined. Your shoes will be defined as search items by their color, size, and so on. Search will be reasonably efficient even in the presence of other objects of similar color or size. Certainly, you will not need to examine every object in the scene as a candidate shoe. In general, you seem to be able to specify one feature per attribute. Thus, search is inefficient if the target is red and yellow and distractors are red–blue and blue–yellow.

As search stimuli become more complex, other factors come into play. For example, scene properties guide the deployment of attention given enough time. Thus, we do not search for people in places that will not support people, for example, the middle of the ceiling (Torralba, A. *et al.*, 2006). It is also possible to search in some ordered manner (e.g., left to right) though, again, this requires time.

2.16.4 Modeling Visual Search

2.16.4.1 Signal Detection Approaches

Visual search can be modeled as a signal detection problem with multiple noise sources. Rather than determining if a particular item is signal or noise, the observer must determine if a signal is present in a whole display. When a few, relatively simple stimuli are presented briefly, signal detection models have proven fruitful. Here observers typically make a two-alternative forced-choice response to a stimulus that can be quite precisely characterized (Verghese, P., 2001). Matters become more complicated when search stimuli remain visible until the observer responds. Now, from the vantage point of decision theory, search becomes a series of decisions. When an observer attends to an item, the observer decides if that item is the target. In signal detection terms, the observer will decide if the signal generated by that item exceeds a target criterion value. If the item is deemed to be the target, the observer responds positively and ends the trial. However, if the signal does not exceed the target criterion, the observer must make a second decision about whether to continue searching or quit with a negative response. This negative response would be made if some other signal exceeds a second, quitting criterion. The complexity of this situation has restricted most signal detection models to the more tractable, brief exposure condition.

2.16.4.2 Physiological Approaches

From a physiological point of view, a central issue is how neurons that might respond to many stimuli in many locations (e.g., inferotemporal cortex neurons) and come to have their activity dominated by one stimulus in one location. Early models had a feedforward structure where early visual processes were not influenced by attention. Attention served as a gate or filter permitting some stimuli to reach later stages. More recent modeling, based on the accumulation of more recent data, proposes that attentional effects can feedback on to the earliest stages of visual cortical processing (Reynolds, J. H. and Chelazzi, L., 2004).

2.16.4.3 Biased Competition

Desimone and Duncan's Biased Competition model is illustrative. When activity from more than one stimulus converges on the same neurons, a competition results that will be won, at least temporarily, by one of the contenders. That victory influences other visual areas so that one stimulus will tend to emerge as the currently favored or attended item. Other theories differ in many details but many share the general notion that the same neural network can settle into multiple states, depending on top-down and bottom-up, stimulus-driven factors.

Experimental evidence has revealed several types of attentional effects on the responses of single neurons. Attention can boost the signal. It can act to exclude noise. The tuning of a receptive field might be changed (e.g., sharpening the tuning for orientation) or the spatial extent of a receptive field might shift or shrink to exclude all but the attended item.

2.16.4.4 Two-Stage Models

In two-stage models, a distinction is made between processing that occurs before the effects of selective attention and processing that comes after. In their early formulations, these models assumed that before and after referred to anatomical location as well as temporal order. As in physiological modeling, more recent versions of these theories have allowed for the possibility of feedback or reentrant processing that would make it possible for one anatomical location to participate in both preattentive and attentive processing of stimuli.

2.16.4.5 Feature Integration Theory

The most influential two-stage model has been Anne Treisman's Feature Integration Theory. It proposed that a limited set of basic features (e.g., color, size, etc.) could be processed in parallel across the visual field. Any operation that required the binding together of two or more of these features would require attention to a single item or, perhaps, a small group of items. Thus, preattentive processes could distinguish a red line from a green one but attention would be required to distinguish a red vertical line from green vertical and red horizontal lines (Treisman, A. and Gelade, G., 1980).

2.16.4.6 Guided Search

Feature Integration Theory was parent to a family of subsequent models. Many of these include the concept of guided search. In guided search, the information gathered about basic features can be used to guide attention toward likely targets. Thus, if an observer is looking for a red letter T, attention will be guided to red letters and not wasted on letters that could never be the target (Wolfe, J. M., 1994). In two-stage modeling, critical questions include the nature of the stimulus attributes that can be processed prior to attentional selection as discussed earlier. Some attributes, like color and orientation clearly fall into the preattentive category. The more interesting and problematic cases are complex and/or learned classes of stimuli like faces and letters.

All models must resolve issues about the nature of selection. What is selected? If objects are selected, how are objects parsed from the background prior to selection? What are the limits on selection? Can more than one item be selected at one time? What does selection do? Does it enhance processing? Does it enable different types of processing?

2.16.5 Memory in Visual Search

Since visual search tasks are typically extended in time, the role of memory becomes an issue. Does the visual system use what has happened in the search so far in order to determine what will happen next? In models that propose that attention is directed from one item to the next in series, the question is whether previously attended items can be resampled during the same search. Classic two-stage models assumed that search proceeded without replacement. Research on the phenomenon of inhibition of return showed that it was harder to get attention and/or the eyes to return to a previously attended/fixated item than it was to move attention or the eyes to a new, unattended item. However, later research showed that inhibition of return was limited to only a few items and several lines of experiments produced data consistent with sampling with replacement – a random deployment of attention without regard to the prior history of search. Current consensus suggests that visual search uses only a very modest memory to limit the revisiting of previously attended items (Horowitz, T. S. and Wolfe, J. M., 2005).

2.16.6 Terminating Unsuccessful Searches

All visual searches must come to an end. Successful searches are easy to understand. Search ends when the target is found. More problematic is the case of unsuccessful search. When does the search end if the target is not found? Models that propose serial selection of items have a simple answer. Search ends when all items have been selected and rejected. However, this only works if observers have perfect memory for attended and rejected items and, as noted above, it is quite clear that this is not the case. Instead, search must end when the observer deems that he has searched for long enough. It proves to be difficult to produce a satisfying definition of long enough. It may be based on elapsed time or on some search metric such as the proportion of items rejected (regardless of whether they have been inadvertently rejected more than once). At present, this has proven to be one of the more recalcitrant problems in visual search.

2.16.7 Conclusion

The problem of unsuccessful searches provides an opportunity to revisit the question of why anyone should care about the mechanics of visual search. As noted at the outset, search is a ubiquitous visual behavior because of limits on visual processing capacity. From a more practical point of view, understanding search is important because our civilization has a knack for creating very difficult artificial search tasks and then insisting that they be done very well. Airport baggage screening and routine medical screening (e.g., mammography) are examples. The stimuli are complex. The targets are rare, so most searches will be unsuccessful. Errors, especially misses, can be a matter of life and death. Advances in the understanding of search may make it possible to design such tasks for greater success.

Glossary

event-related potential (ERP) Voltage fluctuations recorded at the scalp that represent the activity of large neural populations time-locked to measurable events.

Gabor patches Image modified by a filter impulse response defined by a harmonic function multiplied by a Gaussian function.

object-token An episodic trace containing information about the relationship between object features, possibly enriched by object-related knowledge from long-term memory, and addressed via location codes.

single-unit recording Refers to the use of an electrode to record the electrophysiological activity (action potentials) of a single neuron.

Although visual scenes are full of numerous locations, features, and objects, only a small portion of this rich information influences action and memory systems or reaches awareness (Desimone, R. and Duncan, J., 1995; Duncan, J., 2006). Diverse stimuli compete for what we know as visual attention. In previous chapters, attentional selection of spatial locations and features has been examined. However, in natural scenes objects of interest (e.g., a predator observed by its prey) can rapidly change location and specific visual features (such as presented shape and shading). The relevant objects can also be in close visual proximity to, or partially overlapped by irrelevant distracters. In these situations it makes sense to monitor the object itself, not the location or the changeable features of the object. These ecological considerations suggest that competition between objects as distinct entities (and not just a sequence of locations or disconnected features) is a fundamental aspect of visual attention. This conclusion is supported by the experimental evidence reviewed in this chapter. This does not imply that we are not capable of selectively attending to locations or features (which we can), it just means that there are important visual tasks that require attention to objects as wholes.

Given that objects exist in space and have characteristic features, for the goals of this chapter it is necessary to demonstrate in any experiment that it is the object and not only its location or features that are being selected by attention. This has been achieved using three approaches (Valdes-Sosa, M. *et al.*, 1998b; O'Craven, K. *et al.*, 1999; Valdes-Sosa, M. *et al.*, 2000). The first tack is to graphically superimpose distinct objects in order to impede spatial selection. Under these conditions detecting or remembering a stimulus is much better for events related to attended, than to unattended, objects (Neisser, U. and Becklen, R., 1975; Rock, I. and Gutman, D., 1981). Studies using superimposed stimuli have also found that it is easier to divide attention between two features on one object, than

to do so for two features of different objects, even when the two objects are in intimate spatial proximity (Duncan, J., 1984; Vecera, S. P. and Farah, M., 1994; Lavie, N. and Driver, J., 1996; Behrmann, M. *et al.*, 1998). This pattern of results cannot, therefore, be attributed to the time required to shift attention from the location of one stimulus to the location of the other. This is incompatible with the classical spotlight metaphor for spatial attention. However, in the above mentioned experiments the competing objects did not completely overlap, and the findings could therefore be explained by a hybrid mechanism whereby the selection of spatial locations is guided by objects (Vecera, S. P. and Farah, M., 1994).

The second approach is to pit the influence of object organization within visual scenes against spatial proximity. Dividing spatial attention is more difficult for locations farther apart (Egly, R. and Homa, D., 1991), but this spatial effect can be overruled when separate stimuli are perceived as part of the same object (Bundesen, C. and Pedersen, L. F., 1983; Driver, J. and Baylis, G. C., 1989; Kramer, A. F. and Jacobson, A., 1991; Driver, J. *et al.*, 1992). Further, attention spreads more readily between locations within a three-dimensional surface than among points in a different surface, even if they are spatially closer together (reviewed in Nakayama, K. *et al.*, 1995). It is also easier to shift attention between sites within the same figure than between parts of different figures, even for equivalent distances (Egly, R. and Homa, D., 1991; Valdes-Sosa, M. *et al.*, 2004).

The third method is to move the objects in order to dissociate them from a fixed location. Object-based effects have been inferred (Tipper, S. P. *et al.*, 1991; 1994) from the observation that attention can follow the stimuli, instead of being glued to a location. For example, Kahneman D. *et al.* (1992) have shown object-based priming effects: the facilitation in recognition of specific letters by repetition is larger if the repeats are presented within the same moving objects.

Taken together, these experiments provide psychophysical evidence for object-based attention not easily explained by implicit spatial- or feature-based selection. However, modifications of theories about spatial- or feature-based attention could also explain part of the findings. As mentioned above, a flexible attentional spotlight that follows the silhouette of objects would guarantee selection of partially overlapping objects. In the following section we present a situation in which these types of selection are precluded.

2.17.1 Surface-Based Attentional Selection

In this chapter we concentrate on research involving selective attention to one of two superimposed transparent surfaces. This stimulus configuration offers several advantages for understanding object-based attention and has been studied recently with multiple approaches including psychophysical (Valdes-Sosa, M. *et al.*, 1998b; 2000; Rodriguez, V. *et al.*, 2002; Reynolds, J. H. *et al.*, 2003), electrophysiological (Pinilla, T. *et al.*, 2001; Khoe, W. *et al.*, 2005; Rodriguez, V. and Valdes-Sosa, M., 2006), functional magnetic resonance imaging (fMRI; O'Craven, K. *et al.*, 1999; Serences, J. T. *et al.*, 2004), and monkey single-unit experiments (Fallah, M. *et al.*, 2007; Wanning, A. *et al.*, 2007).

Transparency arises when more than one surface lies along a line of sight. Transparent motion is created when different visual patterns (say two sets of dots, or an image of a face and of a house) move in distinct directions within the same region of visual space (see examples in Figure 1). This creates the illusion of two surfaces (or objects) sliding across each other. Each surface is a distinct entity or object-token (Kahneman, D. *et al.*, 1992), and its individuality is preserved by over time and space (Blazer, E. *et al.*, 2000; Valdes-Sosa, M. *et al.*, 2000).

Transparency is ideal for isolating object-based attention since it combines the three approaches outlined above. A spatial spotlight of attention would find it difficult to select only one of the surfaces: it would tend to encompass both or neither. This is especially true for the sliding dots situation. The dots that define two different surfaces are densely intermingled, thus precluding selection of one surface's dots via spatial attention. Finally, stimulus elements are not fixed in location.

Several studies have shown that it is possible to selectively attend to one of two transparent surfaces. Specifically, with sliding dots (Figure 1(a)) is easier to divide attention between the direction and speed of motion of the same surface than between identical attributes for different surfaces (Valdes-Sosa, M. *et al.*, 1998b), which is also true for direction of motion and shape of the moving elements (Rodriguez, V. *et al.*, 2002). Note that since the overlap between the two surfaces is very complete, this data can not be explained by a spotlight of attention, and moreover cannot be explained by object-guided spatial selection.

In one study using transparent surfaces (Valdes-Sosa, M. *et al.*, 2000), subjects discriminated brief

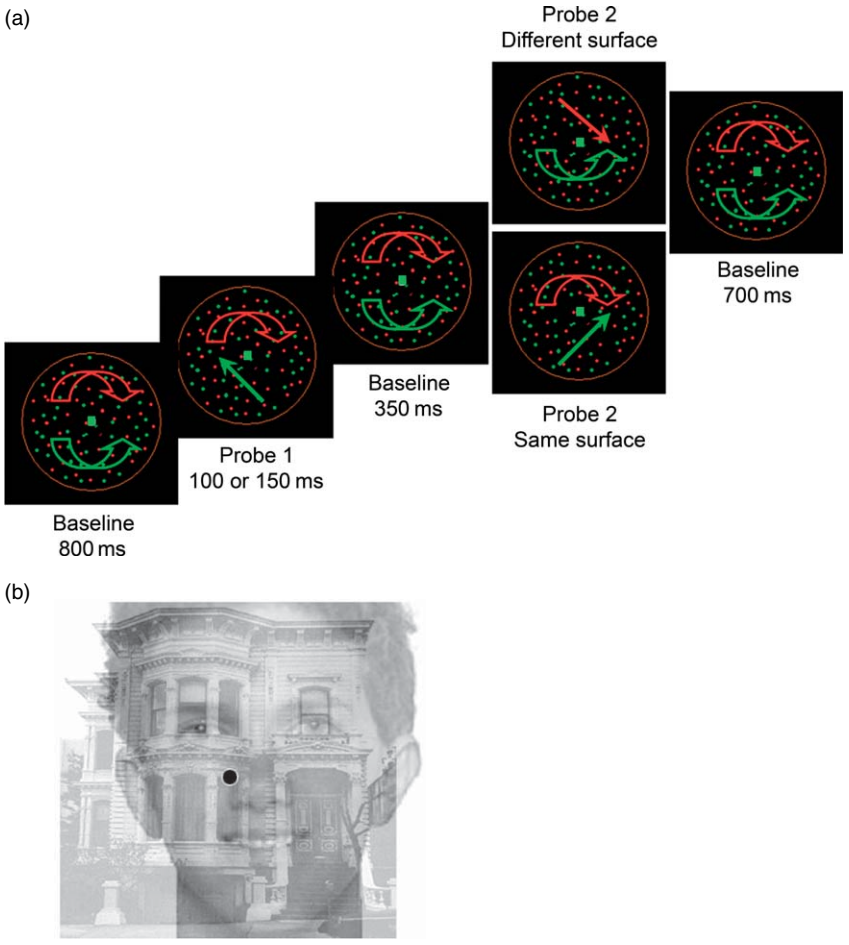

Figure 1 Two experimental designs using transparency for studying object-based attention. (a) Transparent surfaces used by Valdés-Sosa M. *et al.* (1998a; 1998b; 2000), generated by rotating two sets of dots (one red, the other green) in opposite directions. Subjects had to report the direction of two brief changes in the direction of motion of one surface (the second event affected either the same or a different surface than the first, defining two types of trial). (b) Stimuli used by O'Craven K. *et al*. (1999), which consisted in a face transparently superimposed on a house, one moving and the other stationary. Subjects were asked to attend to the face, the house or the motion. (b) Adapted from O'Craven, K., Downing, P. E., and Kanwisher, N. G. 1999. fMRI evidence for objects as the units of attentional selection. Nature 401, 584–587, with permission from Macmillan Publishers Ltd.

changes in the direction of motion of the surfaces. A set of green and a set of red dots rigidly rotated in opposite directions (Figure 1(a)). Subsequently the dots from one surface briefly underwent a translation (T1). This induced the illusion that the surface defined by one pattern of dots suddenly heads in another direction, and rapidly returns to its original motion. After an additional period of rotation, either the same or the other surface underwent another change in direction (T2). Observers reported the direction taken by both targets (T1 and T2). The surface affected by T1 was cued in advance by the color of the fixation point (an endogenous cue for attention), whereas the surface affected by T2 was unpredictable (see two types of trials in Figure 1(a)). Note that T1 itself could attract attention to the surface (this acting as an exogenous cue for attention).

The direction of the first translation (T1) was discriminated accurately under all conditions (Figure 2(a)). Performance was also high for the second translation (T2) if it involved the same surface as T1. In sharp contrast, observers were unable to discriminate T2 when it involved the other surface from T1 and the delay between the two events was short (in the example of Figure 2(a) about 400 ms). Not only is discrimination affected, but it is also difficult to merely detect the T2 motion (Pinilla, T. *et al.*, 2001). Thus, it takes time to shift attention from

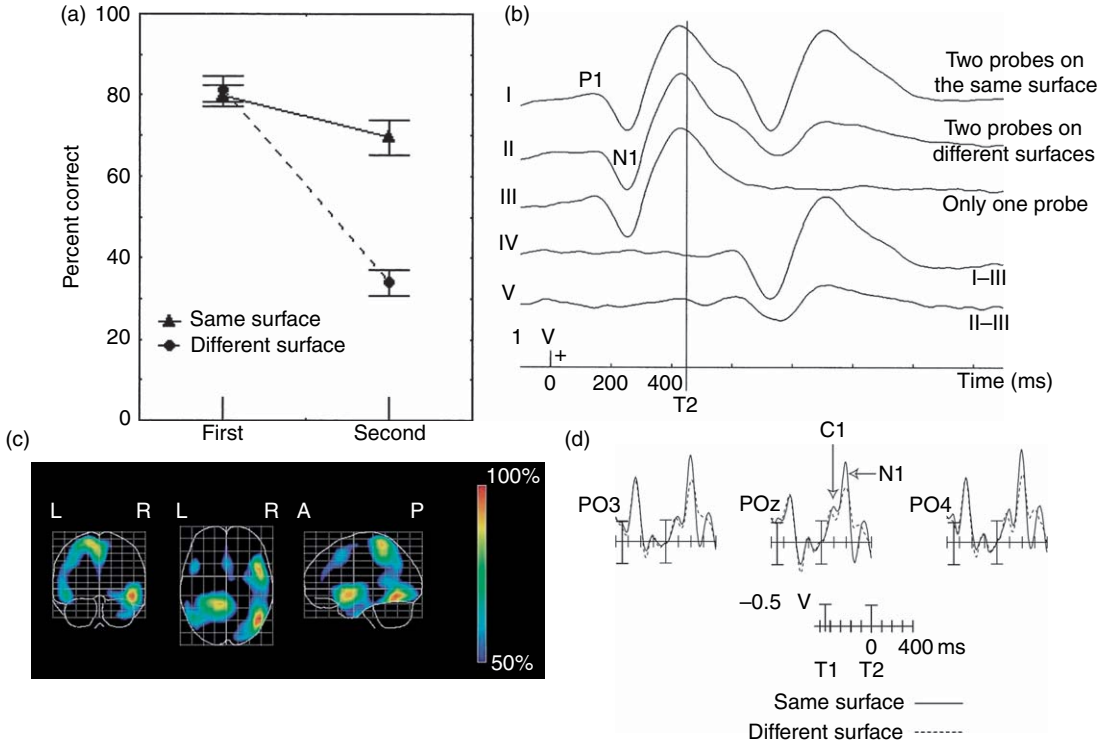

Figure 2 Neural basis of surface-based attention. (a) Attentional interference in the paradigm of Figure 1(a). one surface to another even though they occupy the same region of visual space. Similar results have also been evinced with pairs of superimposed Gabor patches that change orientation, spatial frequency, and color (Blazer, E. *et al*., 2000).

Selective attention for transparent surfaces is not only incompatible with spatial selection. It cannot be explained by the feature selection. The set of possible directions of translation for T1 and T2 were the same for both surfaces, hence motion direction was not the basis of selection. And though color possibly guides attention in these experiments, it is not indispensable, since the between-surface attentional interference is still found when the two surfaces have the same color (Rodriguez, V. *et al*., 2002; Mitchell, J. F. *et al*., 2003).

Further work has shown that these surface-based effects can be found in the absence of endogenous precueing (and thus volitional control of attention), since changes in one surface will automatically attract attention to it (Rodriguez, V. *et al*., 2002; Mitchell, J. F. *et al*., 2003). In contrast, another study (Lopez, M. *et al*., 2004) has shown that endogenous – in absence of exogenous – cueing also enables surface-based selection, so both types of biases can influence in object-based attention.

2.17.2 Neural Basis of Surface-Based Attention

Recent research on the neural basis of attention has been guided by the Biased (or Integrated) Competition model (Desimone, R. and Duncan, J., 1995; Duncan, J., 2006). This model has three basic

ideas; (1) Neural representations of objects compete, with activation of one representation leading to suppression of others; (2) This competition can be biased by stimulus (exogenous) factors like salience or by top-down (endogenous) signals from task context, such as the subjects goals; (3) Despite a disperse cortical representation with different object features and properties coded across multiple brain areas, competition is integrated: dominance in one brain site boosts responses to the same object in other sites. We review evidence on the neural basis of surface-based attention within this framework.

2.17.3 Neural Basis of Competitive Interactions

Considerable effort has been devoted to establishing the brain sites where attentional competition is played out, that is where the unattended inputs are filtered out and where the attended inputs are boosted. In fact, different types of visual attention could operate at different stages of visual processing (Treue, S. and Maunsell, J., 1996; Luck, S. J. *et al.*, 1997; Chelazzi, L. *et al.*, 1998; Duncan, J., 2006). Here we consider this question for visual surfaces which has been studied event-related potentials (ERPs), fMRI, and single-unit recordings in monkeys.

ERPs are voltage fluctuations (recorded at the scalp) that are driven by the activity of large neural populations time-locked to measurable events. Different components of the ERP arise from distinct cortical sites (Hillyard, S. A. and Anllo-Vento, L., 1998). ERPs triggered by the motion-direction changes (T1 and T2) in the sliding-dot paradigm described above were recorded when the time interval between the two events was held at about 400 ms, in other words at a timing when it was difficult to shift attention between the two surfaces (Pinilla, T. *et al.*, 2001). Both the responses contained a negative wave known as N200 (Figure 3), which reflects motion processing (Kuba, M. and Kubova, Z., 1992; Bach, M. and Ullrich, D., 1994; Torriente, I. *et al.*, 1999). This wave begins at about 180 ms after stimulus onset.

The N200 elicited by T2 was significantly reduced when the translations involved different surfaces, relative to when they involved the same surface (Figure 2(b)).This suggests that when attention is allocated to one surface, this reduces the neural response evoked by the translation of the other surface. In experiment just described, it was not possible to find an effect on the earlier P1 component (which

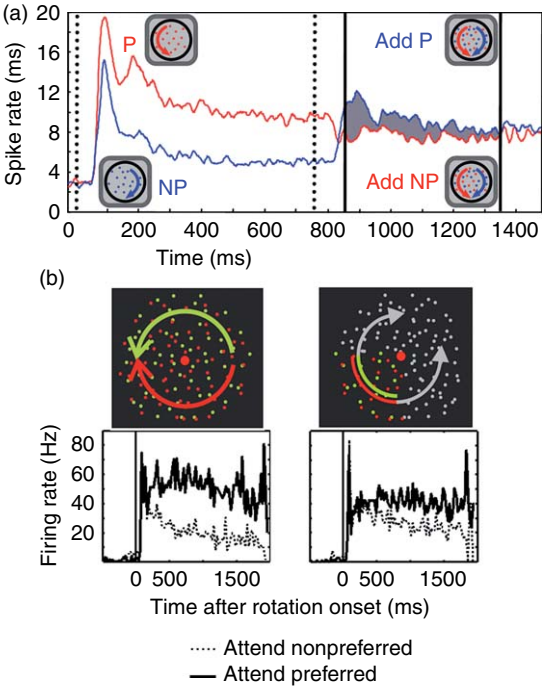

Figure 3 Surface-based attentional effects on unit activity in monkeys. (a) Population average responses in V4 obtained by Fallah M. *et al*. (2007). Red line indicates the response when the nonpreferred surface appeared last, and blue line when the preferred surface appeared last (the last surface attracts attention). (b) Response modulation of an MT neuron (Wanning, A. *et al*., 2007) during the rotation of two transparent surfaces while monkeys selectively attended the cued surface. To the left the surfaces had different colors during all the trial; to the right the surfaces were only colored in a small part of the display. In both cases the neuron responded more to motion in the preferred direction when it was attended. (a) Adapted from Fallah, M., Stoner, G. R., and Reynolds, J. H. 2007. Stimulus-specific competitive selection in macaque extrastriate visual area V4. Proc. Natl. Acad. Sci. U. S. A. 104, 4165–4169 with permission from PNAS. (b) Reprinted from Wanning, A., Rodriguez, V., and Freiwald, W. A. 2007. Attention to surfaces modulates motion processing in extrastriate area MT. Neuron 54, 639–651, with permission.

is clearly modulated by spatial attention). This seems to suggest that surface attention takes place later than spatial selection, but probably does not apply to all situations since when the observer's perceptual load and the time required to sustain attention on one surface is increased, both the N200 and P1 are reduced more than what is typical for spatial selection, with the virtual suppression of both components (Valdes-Sosa, M. *et al.*, 1998a).

The N200 attentional-effect seems to originate from reduced activity of neural generators in visual extrastriate cortex, possibly involving MT

(Rodriguez, V. and Valdes-Sosa, M., 2006), a visual cortical area specialized in motion processing (Albright, T. *et al.*, 1984; Figure 2(c)).The reduction of N200 for unattended surfaces has also been described by Khoe W. *et al.* (2005), who also found smaller P1 and C1 (that peaks at about 92 ms after stimulus onset; Figure 2(d)).This last wave originates in primary visual cortex, suggesting that surface-based attention may influence processing at this early stage (Mitchell, J. F. *et al.*, 2004).

Although the temporal resolution of ERPs is good, localization of their neural sources is not precise. fMRI, despite its slow temporal response, has more spatial resolution. Hence it is reassuring that when observing two transparent surfaces, one due to translating dots and the other to expanding dots, fMRI activity is reduced in V1 when attention was directed to the expanding surface, a less effective stimulus for V1 than translation (Watanabe, K. *et al.*, 1998). This reinforces the idea that attention can modulate activity in the earliest stages of cortical visual processing.

Additional information has been obtained from single-units recordings in awake monkeys. Fallah *et al.* (2007) adapted the paradigm developed for human studies (Valdes-Sosa, M. *et al.*, 1998b; Reynolds, J. H. *et al.*, 2003) for use with monkey observers, while recording in V4, a cortical area specialized for form and color processing. They delayed the onset of one of the surfaces in time relative to the other surface (see Figure 3(a)), taking advantage of the fact that attention is drawn to a newly appearing stimulus (Yantis, S. and Jonides, J., 1984; Yantis, S. and Egeth, H. E., 1997; Gottlieb, J. P. *et al.*, 1998). This is an example of stimulus-driven (or exogenous) attentional capture (Mitchell, J. F. *et al.*, 2003). V4 neurons selective for the color of the attended surface responded strongly, while responses of neurons selective for the unattended stimulus were suppressed. Neuronal responses were driven preferentially by the delayed surface (Figure 3(a)), a difference that resulted from both an increase in response upon addition of the preferred-color surface and a decrease in response upon addition of the nonpreferred-color surface.

Furthermore, Wanning A. (2007) demonstrated a surface-based effects in macaque monkeys performing an attention-demanding direction discrimination task, in a paradigm closer to the one originally employed in humans (Valdes-Sosa, M. *et al.*, 2000). They trained two macaque monkeys to selectively attend one of two overlapping transparent surfaces by matching its color with the fixation spot, a form of goal-driven (or endogenous) attentional control while recording in MT. After a period of reversing rotations, the two surfaces underwent simultaneous translations in different directions. The monkeys reported with a saccade the direction of this translation for the attended surface. Motion selectivity was observed during the rotations and translations, one direction eliciting a robust response and the others a poor response. The MT neurons were driven more by motion in the attended surface than in the nonattended surface for both rotations and translations (Figure 3(b)). This surface-based effect survived when the difference in color between surfaces was removed (Figure 3(b)).

Taken together ERP, fMRI, and single-unit studies indicate that competition between these surfaces is played out at early stages of visual processing (certainly involving extrastriate areas and with weaker evidence for V1), beginning very shortly after stimulus onset.

2.17.4 Neural Integration of Competition

As mentioned above, attention to one attribute of an object – or surface – can entail some degree of obligatory attention to other attributes of the same object (for psychophysical evidence see Duncan, J. *et al.*, 1994; Egly, R. *et al.*, 1994; He, Z. J. and Nakayama, K., 1995; Duncan, J. and Nimmo-Smith, M. I., 1996). In a seminal experiment (O'Craven, K. *et al.*, 1999) observers viewed a sequence of superimposed pairs of semitransparent images (one face and one house, Figure 1(b)). One image was stationary while the other oscillated. In each block observers judged whether an object of one class (house or face) was repeated while ignoring the other class. Responses in FFA (a visual area responding preferentially to faces) and in PPA (a visual area responding preferentially to scenes or houses) were enhanced when attention was directed towards its preferred object type relative to when directed towards the other class (Figure 4(a)).

While providing additional support for object-based attention, this experiment evinced integration of responses from different visual extrastriate areas. Even though motion was ignored in this experiment, activity in the area sensitive to motion (MT+) increased when the attended object was moving relative to when the unattended object was moving (Figure 4(b)). This is consistent with the integrated competition-model: neurons coding features of the attended object assume dominance throughout distributed brain networks (see also Mitchell, J. F. *et al.*, 2004).

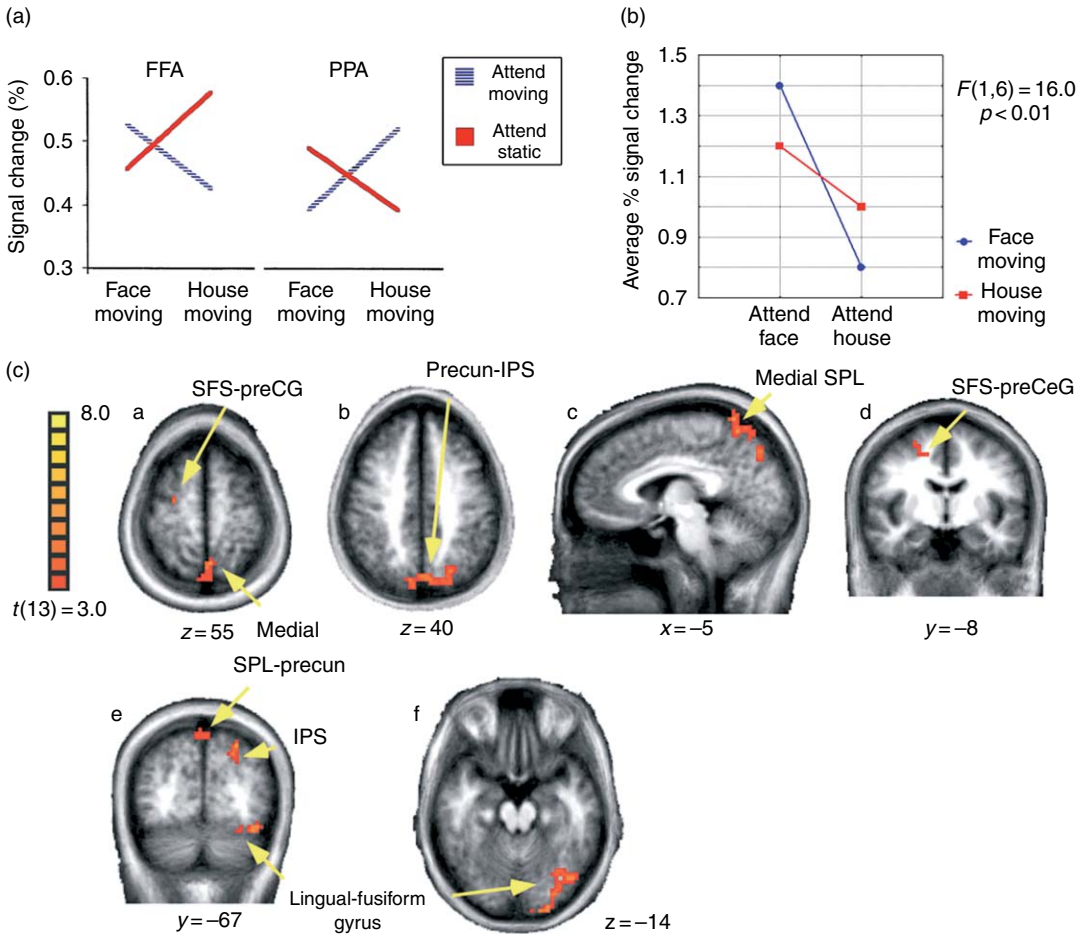

Figure 4 Results obtained by O'Craven K. *et al*. (1999) and Serences J. T. *et al*. (2004) using a transparent superimposition of a house and a face in a functional magnetic resonance imaging (fMRI) design. (a) Means of the peak evoked responses in the fusiform face area (FFA, a visual area responding preferentially to faces) and parahippocampal place area (PPA, a visual area responding preferentially to scenes or houses) as a function of task (attend moving or attend static) and stimulus (face moving or house moving). Magnetic resonance responses were greater to the task-irrelevant attribute of the attended object than to the irrelevant attribute of the unattended object, as predicted by object-based theories of attention motion. (b) Pattern of results in middle temporal/middle superior temporal areas (MT/MST). The signal change was greater when subjects attended to the face or house when they were moving than when they were stationary. (c) Regions exhibiting a greater BOLD response to shift as compared to hold targets in Serences J. T. *et al*. (2004) study. Significant activations were found in right superior frontal sulcus (SFS)–precentral gyrus (PreCeG) and medial superior parietal lobe (SPL)–precuneus (a), left intraparietal sulcus (IPS) (b), medial SPL–precuneus (c), right SFS–PreCeG (d), left IPS (e) and left lingual–fusiform gyrus (f) motion. (a) Adapted from O'Craven, K., Downing, P. E., and Kanwisher, N. G. 1999. fMRI evidence for objects as the units of attentional selection. Nature 401, 584–587, with permission from Macmillan Publishers Ltd. (b) Based on data from O'Craven, K., Downing, P. E., and Kanwisher, N. 2.17.5 Neural Control Signals (Bias Inducers)

We have seen stimulus factors (like the sudden onset of a surface or object luminance) can bias competition in favor of one surface. Top-down, endogenous, signals like task instructions (e.g., look out for the red surface) also can tip the balance in favor of one object.

One study of endogenous signals with transparent surfaces (Serences, J. T. *et al*., 2004) has built on the face/house design previously described (O'Craven, K.

et al., 1999). In this case, the stream of superimposed house/face pairs were periodically (1/s) morphed so each object was changed into another exemplar of its class. Attention was directed to either the house or the face stream as the observer searched for particular memorized faces or houses. Some targets signaled that attention should remain on the attended stream; other targets signaled that attention should be shifted to the other stream.

In the superior parietal lobe (SPL) there was a transient increase in fMRI activity during switch trials (both face-to-house and house-to-face) that was absent during trials where attention was maintained on the same stream (Figure 4(c)). Studies of shifts of spatially based attention show equivalent results in the SPL suggesting that endogenous control signals operate similarly for different types of attentional selection. If this is the case then evidence for sustained control signals should be found for object-based attention in frontal and inferior parietal lobe, as has been the case for space-based attention (Corbetta, M. and Shulman, G. L., 2002; Serences, J. T. *et al.*, 2004).

2.17.6 Other Approaches to Object-Based Attention

In this review we have concentrated on studies of object-based attention that superimposed transparent surfaces to preclude spatial selection. We suspect that the strong perceptual rivalry set up between competing surfaces (akin to binocular rivalry) has assisted in reaping clear attentional effects with different experimental tools. The other approaches to study object-based attention have not been reviewed because of limited space. However, we mention a promising series of studies that take advantage of the greater ease observers have in shifting attention between sites within the same figure than between parts of different figures in a design originally described by Egly R. *et al.* (1994; see also Valdes-Sosa, M. *et al.*, 2004). Several groups (He, X. *et al.*, 2004; Martinez, A. *et al.*, 2006; 2007) have shown that stimuli related to irrelevant parts of an attended object are associated with larger N1 (but not P1) components than any part of an unattended object (i.e., attention spreads to all parts of cued object). fMRI activity within the lateral occipital complex is also modulated by this object-based spread of attention (Mueller, N. G. and Kleinschmidt, A., 2003; Martinez, A. *et al.*, 2006; 2007). Further study is needed to establish the relationship between this type of object-based effect and that found for transparent motion. Nonetheless, the former effects are compatible with object-guided spatial selection. This is consistent with the smaller N1 found for irrelevant relative to relevant locations within the attended object. In contrast, results with transparent motion cannot be explained by object-guided spatial selection.

2.17.7 Unanswered Questions

Despite solid evidence that object-based attention exists, and successful first steps in understanding its neural basis, there are several fundamental but poorly understood issues that require work in the future. Perhaps the most puzzling of these issues is how the integration of object codes is achieved. This is also known as the binding problem. Further discussion of this important issue is not possible here (readers are referred to Roskies, A. L., 1999; Hommel, B., 2004). Among other issues that need to be examined are the relative time course of different attentional mechanisms (endogenous versus exogenous; space-, feature- and object-based attention). Finally, the involvement of V1 (primary visual cortex) in object-based attention should be further examined, given the tantalizing evidence (mentioned in the chapter) that surface-based attention modulates the activity of this area, evidence which contrasts with previous findings ruling out this modulation for spatial attention (Martinez, A. *et al.*, 1999).

2.18.1 Introduction: Active Vision – Saccadic Eye Movements and Visual Perception

Unlike a camera, which passively and instantaneously captures light onto film or a sensor, the primate visual system extracts information from the environment actively and sequentially. Under natural circumstances, behaviorally relevant visual targets draw a viewer's attention, which is typically shifted overtly by way of a saccadic eye movement (saccade). Saccades are the rapid shifts in the direction of gaze that are used to position the tiny portion of the retina with the highest spatial acuity, called the fovea, onto targets of interest. The repositioning of the fovea via saccades occurs about four to five times per second and represents the most crucial of visually guided behaviors. It is apparent from our remarkable ability to read text, hit a pitched baseball, or scan for a familiar face in a crowd that the goal of the saccadic system is more than simply to move the eyes randomly across the visual scene. Indeed, over the past 30 years or so, neurophysiological and psychophysical evidence has revealed the extensive interconnectedness of the saccadic system and the visual and cognitive machinery of the brain.

Considerable evidence demonstrates that saccadic eye movements both reflect and influence the perception of visual stimuli. For example, the Muller–Lyer illusion (Figure 1) is well known to have a robust effect on the judgment of the lengths of two lines. In the illusion, lines feathered with outward-going segments at the ends (top) tend to appear longer than those feathered with inward-going segments (bottom) despite the fact that both lines are of equal length. Interestingly, when subjects freely view the two lines and make voluntary saccades while judging their lengths, the metrics of the individual saccades used to scan the lines are different, and reflect the perceptual illusion. Saccades made between endpoints of the line mistakenly perceived to be longer have greater amplitudes. This observation, made originally by Yarbus A. L. (1967), reveals the tight coupling between the perception of visual stimulus features and the movement commands issued to target them.

More recently, Kowler and colleagues have investigated the correlation between the metrics of saccades and perception by comparing the perceived centers of complex visual targets to the landing points of the saccades required to visually acquire the objects (Vishwanath, D. and Kowler, E., 2003). While isolated saccades were influenced by local object features more than was perception, the perceived centers of the visual objects and the landing points of naturalistic scanning saccades were remarkably similar. Other investigators have found that saccades made to targets that evoke a strong perception of visual motion robustly influence saccade metrics. For example, saccades made to fields of coherently drifting dots are strongly biased in the direction of the perceived motion, despite the fact that the aperture itself is stationary (Moore, T. *et al.*, 2001; Gross, C. G. *et al.*, 2004; Xiao, Q. *et al.*, 2006).

Saccades not only reflect visual perception but also appear to shape and enhance it. He P. and

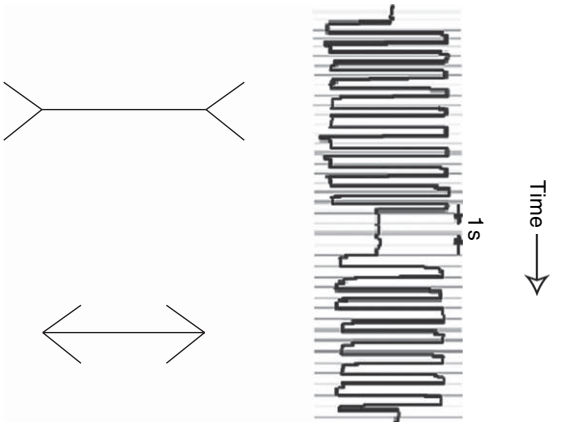

Figure 1 The influence of a visual illusion on the metrics of saccades. Left: An example of the Muller–Lyer illusion is shown in which two equally long horizontal lines appear to be of different lengths due to the direction of attached line segments. Subjects were instructed to judge the lengths of the lines while eye movements were recorded. Right: The traces show the horizontal position of a subject's gaze during saccades made between the ends of the two illusory stimuli. Note that the amplitude (left-to-right) of the top set of saccades is greater than that of the bottom set, which correspond to the top and bottom Muller–Lyer stimuli, respectively.

Kowler E. (1992) examined the effect of saccades on human perception of polygonal patches of texture patterns presented foveally against a differently textured background. They found that the ability to accurately determine the size and shape of the target polygonal patch was improved when the subject was allowed to saccade freely, despite the fact that individual texture elements were easily identifiable under fixation alone. This benefit of saccades on perception supports previous reports of such improvement, such as the enhancement that accompanies saccades when counting scattered visual targets (Kowler, E. and Steinman, R. M., 1977). While some studies indicate that the saccadic and visual–perceptual representations are not completely identical and can be influenced independently (e.g., Aglioti, S. *et al.*, 1995), the relationship between them clearly suggests overlapping mechanisms.

2.18.2 Visual Representations and the Guidance of Saccadic Eye Movements

The links between perception and saccades suggest that the representation of a stimulus in visual cortex might be involved not only in determining the way in which the stimulus is perceived but also in helping the saccadic system specify an appropriate eye movement to foveate the stimulus. Most of what is understood about how the visual world is represented by neurons within the primate brain is derived from studies of the macaque visual system. The macaque visual cortex is composed of a large array of separate maps of the visual field (Felleman, D. J. and Van Essen, D. C., 1991). These maps can be divided into two distinct sets or processing streams, one ventral and one dorsal (Ungerleider, L. G. and Mishkin, M. 1982) (Figure 2(a)). Early electrophysiological studies of monkey parietal cortex, within the dorsal stream, found single neurons that exhibited bursts of activity immediately prior to the execution of saccades to visual targets (Hyvarinen, J. and Poranen, A., 1974; Mountcastle, V. B. *et al.*, 1975). Mountcastle V. B. *et al.* (1975) described these cells as part of "a command apparatus for operation of the . . . eyes within immediate extrapersonal space." Later, Andersen and colleagues described the saccade-related activity in parietal cortex as being "involved in the transformations of visual information for the planning of saccadic eye movements" (Barash, S. *et al.*, 1991). Rather than a motor signal or a visual signal, the activity was interpreted as serving a role in transforming visual representations into visually guided saccadic eye movement commands. More recent evidence has confirmed that although some visual areas of parietal cortex are clearly involved in representing the behavioral relevance, or salience, of visual targets (Gottlieb, J. P. *et al.*, 1998; Bisley, J. W. and Goldberg, M. E., 2003; Ipata, A. E. *et al.*, 2006), the activity of parietal neurons is nonetheless predictive of the goal and time of initiation of saccades (Ipata, A. E. *et al.*, 2006).

Evidence of an accompanying role of ventral stream visual areas in the programming of saccades began with the early observations of Fischer and Boch, who conducted studies of area V4 neurons in monkeys trained to make saccades to visual targets (Fischer, B. and Boch R., 1981; Boch, R. and Fischer, B., 1983). They found that the visual responses of neurons in area V4 are enhanced prior to saccades made to visual targets appearing in a neuron's receptive field (RF). Chelazzi L. *et al.* (1993) subsequently showed that the activity of neurons in inferior temporal cortex is also enhanced when a visual stimulus was chosen as the target of a saccade. The enhancement of visual activity of ventral visual cortical neurons has also been described during free viewing of natural scenes. Gallant J. L. *et al.* (1998) pioneered the study of visual cortical representations in freely viewing monkeys. During free viewing, monkeys are

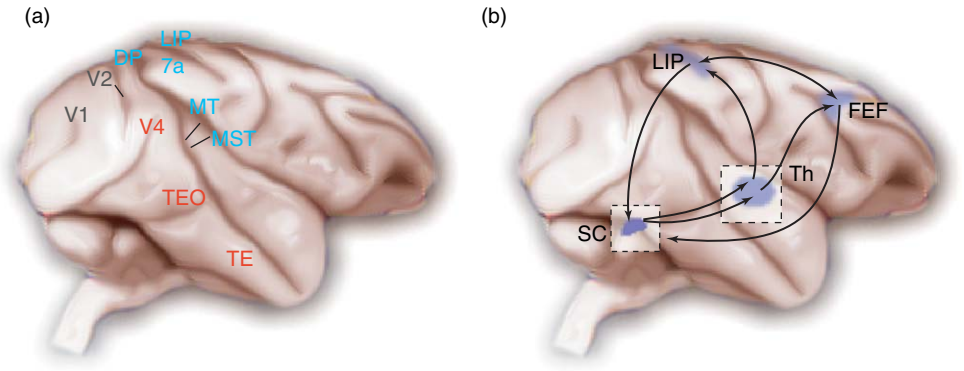

Figure 2 Visual cortical areas and visuosaccadic structures of the macaque monkey brain. (a) Some of the many separate visual areas within cortex. Labels in red denote some of the ventral stream visual areas, while labels in blue show some in the dorsal stream. (b) The principal structures involved in the programming and execution of visually guided saccades and their connections, namely, the lateral intraparietal area (LIP), the frontal eye field (FEF), and the superior colliculus (SC). Forward projections from the SC to the LIP and the FEF are via thalamic nuclei (labeled Th), namely, the pulvinar and mediodorsal nucleus, respectively. The dotted box surrounds the two subcortical structures, SC and Th.

permitted to scan large field displays with saccades. Because the majority of visual RFs in cortex are fixed to a particular retinal location, saccades shift the RFs from one location to the next every time a saccade is made. Gallant J. L. *et al.* (1998) recorded from single neurons in visual areas V1, V2, and V4 during free viewing and found that nearly half of the neurons had activity that was modulated during eye movements, even if one accounted for the physically shifting RFs. Similarly, Sheinberg D. L. and Logothetis N. K. (2001) investigated perisaccadic activity in inferior temporal cortex using a free-viewing paradigm in which a monkey was instructed to find a visual target embedded within a natural scene. During this task, many neurons within the temporal cortex were found to become active just prior to a saccade that targeted an RF stimulus, but not prior to saccades that would target stimuli outside of the RF.

Moore T. *et al.* (1998) followed up on the studies of Fischer B. and Boch R. (1981) and found that the presaccadic enhancement of V4 visual responses is selective for the features of the saccade target, just as is the initial response of the target in the RF, and thus demonstrated that the enhancement itself contained both visual and motor information. Thus, for example, presaccadic enhancement is greatest prior to saccades to targets presented at a particular V4 neuron's preferred orientation. To address the significance of the presaccadic signals in V4, Moore T. (1999) examined the metrics of saccades made to targets of varying orientation and found that saccades on trials with more robust presaccadic activity were more faithfully distributed along the axis of orientation than were saccades on trials with weaker activity. Thus, similar to what is more well established within the dorsal visual stream, neurons in the ventral stream appear to play at least some role in the preparation of saccades.

To summarize, neurophysiological evidence to date reveals an interaction of visual representations with saccade plans that is distributed throughout visual cortex. This evidence suggests that the parameters of visual stimuli and the parameters of saccades are specified simultaneously via those interactions every time a particular stimulus is targeted, thus providing the basic machinery for visual exploration during the overt orienting of attention (Moore, T. *et al.*, 2003). Next, we consider a similar basis for covert orienting.

2.18.3 Psychophysical Links between Covert Spatial Attention and Saccade Preparation

Early physiologists and theorists of cognition hypothesized that the mechanisms controlling eye movements must exert an influence on visual perception (von Helmholtz, H., 1866/1962) and might provide the basis for some aspects of visual attention (Ferrier, D., 1890; Ribot, T. H., 1980). Numerous modern psychophysical studies have revealed evidence linking selective attention and the preparation of saccades. Generally, this evidence suggests one or both of two possibilities: that visual spatial attention influences saccade preparation and that saccade preparation influences the deployment of visual spatial attention. The most classic

demonstration of the influence of directed attention on saccades was provided by Rizzolatti G. *et al.* (1987). In this study, the authors examined how covert attention perturbed saccade trajectories. Subjects were instructed to initiate saccades to a location in one half of the visual field according to cues presented in the other half. The cues could be presented in one of several locations in the cued half of the visual field. The authors found that saccade trajectories were systematically deviated according to the location of the covertly attended (i.e., cued) location. Thus, the deployment of covert attention can perturb saccade programming. The above observation and similar findings from other investigators (e.g., Kowler, E. *et al.*, 1995) are frequently cited as evidence for what is commonly referred to as the premotor theory of attention, a more modern incarnation of the early hypothesis of an oculomotor basis of attention (e.g., Ferrier, D., 1876).

To address the role of saccade preparation in the deployment of attention, Hoffman J. E. and Subramaniam B. (1995) had subjects make saccades to a location while also detecting visual targets presented prior to the eye movement. These authors found that target detection was typically best at the location of planned saccades and that subjects were unable to completely dissociate the attended and saccade locations. These results suggest that the preparation of saccades to a location deploys attention to that location. Deubel H. and Schneider W. X. (1996) found similar results and concluded that a single mechanism must drive the selection of objects for perceptual processing and the information needed to drive the appropriate saccadic response.

Although these psychophysical studies provide a sound rationale for the hypothesis that oculomotor and attentional circuits have a common neural substrate, they cannot rule out the alternative view that these are two distinct and independent systems. In recent years, neurophysiological studies have taken a more direct approach to this problem by perturbing neural signals within oculomotor structures and examining the effects of those perturbations on spatial attention. These structures include the frontal eye field (FEF) and the superior colliculus (SC), both having a known role in the programming and triggering of saccades. The approach of directly manipulating signals in these areas addresses the causal relationship between neural activity in oculomotor circuits and shifts of spatial attention.

2.18.4 Evidence of Oculomotor Involvement in Spatial Attention

2.18.4.1 Attention Deficits Following Brain Damage

One source of evidence for an involvement of the saccadic system in visual spatial attention comes from the cognitive impairments that ensue when areas of the brain that control eye movements are damaged. The earliest evidence comes from the nineteenth-century physiologist Sir David Ferrier (1890) mentioned above. Perhaps Ferrier's most noteworthy discovery was that electrical stimulation of a region within frontal cortex could elicit contraversive, conjugate movements of the eyes (Ferrier, D., 1876). This region later became known as the frontal eye field and is known to play a crucial role in the planning and execution of visually guided saccades (Bruce, C. J. *et al.*, 1985; Schall, J. D. and Hanes, D. P., 1993; Tehovnik, E. J. *et al.*, 2000). Ferrier also performed a series of lesion experiments in monkeys in order to localize functions within specific brain regions. Following lesions of frontal cortex, including the FEF, he observed that monkeys were impaired in their ability to voluntarily direct gaze toward objects, a deficit he described as tantamount to a "loss of the faculty of attention." He went on to propose that "the power of attention is intimately related to the volitional movements of the head and eyes." His early finding that frontal cortical lesions disrupt attention and eye movements was corroborated by later lesion studies in which unilateral ablations were performed in a restricted region of frontal cortex, corresponding approximately to the FEF (Welch, K. and Stuteville, P., 1958). These studies reported deficits in monkeys' ability to orient and respond to salient objects (food and frightening stimuli) in the contralateral visual field. Latto R. and Cowey A. (1971) were the first to quantify these visual deficits by training monkeys to release a lever in response to a flash of light presented at different locations throughout the visual field and examining how performance on this task was affected by lesions to the FEF. They found that unilateral FEF removal transiently impaired performance in the contralateral visual field. The animals were not blind, as they could still respond correctly on a fraction of trials; however, they were far more likely to fail to respond to stimuli presented in

the affected hemifield than elsewhere. Latto R. and Cowey A. (1971) suggested that the FEF might normally modulate the visual system according to eye position and that this could explain the fact that such small lesions were able to produce such pronounced deficits.

More recently, studies have used reversible pharmacological inactivation to temporarily disrupt neural activity in a number of structures with known roles in the control of saccades, including the FEF (Wardak, C. *et al.*, 2006), the SC (McPeek, R. M. and Keller, E. L., 2004), and the lateral interparietal area (LIP) (Wardak, C., *et al.*, 2002). Generally, inactivation of these structures increases the time it takes an animal to initiate saccades to visual targets appearing in the affected part of space (Hikosaka, O. and Wurtz, R. H., 1986; Lynch, J. C. and Mclaren, J. W., 1989; Sommer, M. A. and Tehovnik, E. J., 1997). In addition, the inactivation also impairs performance on attention-demanding tasks in the affected part of visual space when other distracting stimuli are present. Performance on tasks without an attentional demand, such as those using a single visual stimulus, is not affected. Thus, to date there is good evidence that brain structures involved in controlling visually guided saccades also play a causal role in directing visuospatial attention.

2.18.4.2 Neurophysiological Correlates of Attention in Saccade-Related Brain Structures

The deficits following lesions and reversible inactivation of saccade-related structures suggest that neurons in these areas are critically involved in the allocation of attention across space. Evidence from recording studies that monitor the activity of single neurons in different saccade-related areas is consistent with this interpretation. Early studies showed that the responses of SC neurons to visual stimuli are enhanced only when those stimuli are used as targets for saccades (Goldberg, M. E. and Wurtz, R. H., 1972). Subsequently, similar results of a dependence of enhanced visual activity were obtained in the FEF (Goldberg, M. E. and Bushnell, M. C., 1981). However, recent studies involving more sophisticated covert attention paradigms have found that neurons in the FEF and the SC exhibit attention-related modulation that is not tied specifically to saccade initiation (Ignashchenkova, A. *et al.*, 2004; Thompson, K. G. *et al.*, 2005) similar to what is observed in LIP (Bushnell, M. C. *et al.*, 1981) and throughout extrastriate visual cortex (Reynolds, J. H. and Chelazzi, L., 2004).

2.18.4.3 Driving Attention

The results from recording and lesion studies suggest that spatial attention is driven by neural activity from saccade-related structures. If this is the case, then it should be possible to direct attention by driving neural activity within these structures. Recent studies have used electrical microstimulation to test the hypothesis that saccade-related circuits play a causal role in driving attention to particular locations in the visual field. While it had long been known that microstimulation of the FEF and the SC can elicit saccades, Moore T. and Fallah M. (2001) were the first to examine the effect of microstimulation on visual attention. They found that when they stimulated sites within the FEF using currents that were too low to evoke a saccade, they could nonetheless enhance monkeys' ability to detect changes in a visual target. Importantly, the improvements observed with microstimulation were dependent on the target of attention being positioned at the location to which suprathreshold microstimulation would shift the monkey's gaze (Moore, T. and Fallah, M., 2001; 2004). Thus, it appeared that by increasing the likelihood that the monkey would foveate a location in visual space, the microstimulation also enhanced the animal's ability to process visual events there. Subsequently, two other studies reported similar enhancements in visual spatial attention following subthreshold microstimulation of the SC (Cavanaugh, J. and Wurtz, R. H., 2004; Muller, J. R. *et al.*, 2005). In both cases, the performance-enhancing effects of microstimulation were spatially dependent as in the FEF studies.

The effect of electrical microstimulation of the FEF and the SC on visual spatial attention performance suggests that during stimulation, visual representations of spatially correspondent stimuli are enhanced compared to those of stimuli at other locations. As mentioned earlier, a wealth of evidence has established that correlates of visual attention can be observed throughout much of macaque visual cortex (Reynolds, J. H. and Chelazzi, L., 2004): visual responses to RF stimuli are typically enhanced when a monkey is trained to covertly attend to them. Thus, one might expect that microstimulation of the FEF or the SC will likewise result in the enhancement of the responses of visual cortical neurons to RF stimuli. This was the hypothesis posed by Moore T. and

Armstrong K. M. (2003), who paired FEF microstimulation with single-neuron recording in extrastriate area V4. Specifically, they studied the impact of subthreshold microstimulation of FEF sites on the visual responses of V4 neurons with RFs that were either overlapping or nonoverlapping with the spatial location represented at the FEF site. They found that following very brief trains of FEF stimulation (20–50 ms) visual responses were enhanced at overlapping locations in the visual field, whereas they were suppressed at nonoverlapping locations. Furthermore, this attention-like modulation was greatest when there was another distracter stimulus presented outside of the V4 neuron's RF. A subsequent study also found that FEF microstimulation can alter the structure of V4 RFs and can bias V4 responses in favor of one of two RF stimuli (Armstrong, K. M. *et al.*, 2006). These changes in V4 responses are very similar to what has been observed in the same area during voluntary attention (Moran, J. and Desimone, R., 1985; Reynolds, J. H. *et al.*, 1999). Together, the above results suggest that microstimulation of oculomotor structures drives covert attention and its correlates in visual cortex and that indeed, as speculated by Latto R. and Cowey A. (1971), visual spatial attention seems to be driven by feedback from the oculomotor system onto visual cortical areas, and this feedback influence may exist in order to modulate processing according to eye movement plans.

In summary, recent neurophysiological work has directly addressed and found much evidence of a role of saccade mechanisms in directing covert visual spatial attention. This evidence appears to support the conclusion that the neural mechanisms of covert and overt spatial attention are identical with respect to the influence of the saccade plan on visual representations. Although it is clear that some different mechanisms must be in effect when attention is directed overtly, that is, when planned movements are triggered and shifts in gaze are actually carried out (Awh, E. *et al.*, 2006), than when it is directed covertly, recent results suggest that those differences are less important than the similarities.

2.18.5 Conclusions

Unlike the passive camera, the primate visual system extracts information from the environment actively and sequentially by way of saccadic eye movements. Every saccade must accurately position targets of interest onto the fovea where visual acuity is greatest, and this takes place four to five times per second. We have described the psychophysical and physiological evidence of highly interconnected mechanisms for visual perception and saccade preparation. This evidence includes correlates of saccade planning within visual cortex as well as changes in visual cortical signals following perturbations of saccade representations and thus argues for a reciprocal relationship between the coding of visual features and of saccade metrics. Furthermore, recent evidence suggests that this reciprocal interaction serves as the basis for covert spatial attention.

2.19.1 Introduction

The term salience (or saliency) has an easy intuitive definition. We say that an object is salient if it is easily noticed or appears to jump out at us from the surround. Salient objects are those that attract our attention automatically, apparently with little effort on our part.

Since the time of William James, psychologists have recognized that attention may be captured in stimulus-driven manner (i.e., may be attracted to certain objects by virtue of their intrinsic physical properties alone) or may be deployed in voluntary fashion (i.e., may be allocated to objects that are known to be significant in a specific context). Recast in different terms, this means that saliency is determined both by stimulus-related and by task- or observer-related factors. Stimulus-related factors define the physical conspicuity of an object, that is, the contrast between the physical properties of the object and those of the surrounding environment. A red apple is salient in a pile of green apples because its color contrasts strongly with that of the surround; the same apple is not salient in a pile of other red apples because its color is no longer unique in this context. Task- or observer-related factors describe the state (goal, expectations, action plans) of the observer. In an elegant series of experiments, Mack A. and Rock I. (2000) illustrated the distinction between physical conspicuity and attentional weight. Mack and Rock showed that human observers may fail to notice even objects that are highly conspicuous if these objects are entirely unexpected and unrelated to an ongoing task, a phenomenon so striking that it was labeled inattentional blindness. Both physical conspicuity and behavioral state determine the subjective salience of a given object in a given context.

Just as physical and behavioral factors come into play in our intuitive notion of saliency, these factors continuously interact in visual areas of the brain. Physical conspicuity strongly influences neural activity starting in the retina and through higher-order visual areas. Behavioral factors also influence neuronal responses, and these influences become progressively stronger in higher-order visual and visuomotor association areas that link visual percepts with behavior. The attentional weight of an object is computed in the brain through continuous interactions among lower and higher-level visual representations.

2.19.2 Stimulus and Task-Related Factors in Early Vision

Starting at the earliest levels of the visual system the brain preferentially encodes loci of luminance contrast in the visual input. Many bipolar cells and ganglion cells in the retina as well as neurons in the lateral geniculate nucleus and primary visual cortex (V1) respond not to absolute levels of illumination but rather to luminance contrast within their spatial receptive field. These neurons have antagonistic center-surround organization, with ON-center cells preferring stronger light intensity in the receptive field center and weaker intensity in the surround, and OFF-center neurons preferring the opposite gradient. Neurons in V1 have elongated receptive fields and respond optimally for contrast edges of specific orientation, thus encoding contours or edges that segment the visual input into objects or surfaces.

In these early visual areas sensitivity to contrast is not generally thought of in terms of physical conspicuity, but rather as a strategy for compressing visual information or for efficient visual encoding. For instance, to encode a uniformly lit shape it is more parsimonious to represent the boundary of the shape

(which contains multiple, possibly abruptly changing orientations) than to represent the shape's interior, which contains essentially redundant (uniform) luminance information. Loci of high contrast are highly informative in the initial encoding of a visual scene. The fact that high-contrast loci also tend to attract attention may reflect an adaptation of the visual system to give priority processing to features that are most useful in interpreting the visual input.

Converging evidence from neurophysiological and psychophysical studies shows that elementary computations that extract informative visual features are not carried out in an encapsulated early vision system. Instead, these computations continuously interface with behavioral systems, and they are both influenced by and in turn influence mechanisms of voluntary attention.

A first line of evidence for this idea is the finding that, while elementary visual computations in early visual areas are to some extent automatic, these computations can nevertheless be influenced by attention. The interacting role of automatic and voluntary processes is best illustrated by an experiment by Charles Gilbert and his colleagues in primary visual cortex (V1) of the monkey. In this experiment, Li W *et al.* (2006) tested the responses of V1 neurons to linear contours embedded within uniform texture backgrounds in monkeys. Backgrounds were composed of randomly oriented line segments, while contours were formed by aligning a small number of these line segments along a collinear, straight path. The monkey's task was to detect the presence of a continuous contour. Even though V1 neurons have small receptive fields that typically encompass only one line segment, neurons were influenced by the broader visual group of which that segment was a part: firing rates were higher if the line segment inside the receptive field was part of a continuous contour than if it was part of the noisy background texture. Further, when the saliency of the contour was manipulated by changing the number of aligned elements or the spacing between these elements V1 responses increased in proportion to the salience (detectability) of the contour. To see to what extent these responses depended on top-down attention (on the monkey's explicit strategy of looking for the contour), Li W. *et al.* (2006) also probed V1 responses in condition in which monkeys performed a different discrimination task while a (now task-irrelevant) contour appeared in the receptive field. V1 neurons continued to signal the presence and salience of this contour but had lower overall firing rates relative to the attended condition.

This experiment makes three important points. First, although V1 neurons are exquisitely tuned for local visual features, their responses reflect processes of contour integration and grouping that pull out salient contours on a larger spatial scale. Second, contour integration occurs to some extent automatically, regardless of explicit behavioral strategy. This is consistent with findings that sensitivity to contrast and local orientation is robust even in anesthetized animals, and thus that it is, to some extent, a hard-wired property of early visual representations. However, contour integration is facilitated by voluntary or top-down attention showing that voluntary factors can impact the extraction of visual features even at early stages of visual processing.

Consistent with the findings of Li W. *et al.* (2006), psychophysical studies confirm that the detection of even the most elementary visual features requires some amount of attention. The paradigmatic easy visual task is pop-out detection – the ability to detect a unique, highly conspicuous element in a uniform background (i.e., a red apple in a pile of green apples). Initially pop-out detection was proposed to be accomplished by automatic feature extraction mechanisms in early visual areas, and to operate without the need for directed attention. However, Ken Nakayama and his colleagues showed that pop-out detection performance declines dramatically if subjects simultaneously perform a very demanding letter identification task (Joseph, J. S. *et al.*, 1997). In line with the findings of Mack A. and Rock I. (2000), even the detection of a highly salient object commands some attentional resources. The attentional requirements of a pop-out task are very low, so that, to effectively influence performance on this task a very difficult competing task had to be used. Nevertheless, when an appropriate challenge is applied it becomes clear that even a simple task such as pop-out detection demands attention.

A final line of evidence from neurophysiological recordings confirms the idea that a visible object makes automatic demands on a limited pool of neuronal resources by virtue of its presence, or intrinsic salience alone. Single neuron recordings in monkeys and functional magnetic imaging in human subjects show that in extrastriate visual cortex the neural representations of multiple objects compete, so that neurons show lower, not higher, firing rates as more objects are added to a display. In areas V2 and V4 (which lie at somewhat higher levels than area V1)

neural responses to two simultaneously presented visual stimuli interact, so that the information that neurons transmit about the features of each object is corrupted in the presence of other objects. These competitive interactions occurred in the absence of voluntary attention, showing that they can be triggered merely by the intrinsic salience of a visual entity. The mere presence of an object in the field of view can command neural resources, and these resources become increasingly significant when the object is selected by voluntary, top-down attention.

In sum, no sharp border exists in the brain between processes reflecting physical conspicuity and those reflecting attentional weight. Aspects of the visual input that are perceived as salient are preferentially encoded starting in the retina and primary visual cortex and become attentional attractors. The extraction of these salient entities is in part automatic and in part dependent on top-down attention. The entities created by early visual mechanisms – objects, boundaries and surfaces – pose intrinsic demands, automatically competing for a pool of limited neuronal representations.

2.19.3 Behavioral Salience in Higher-Order Attention-Related Areas

While neurons in striate and extrastriate cortex show the influence of behavioral state, these top-down effects are thought to originate outside the visual system itself, in higher-order visual association areas in the frontal and parietal lobes. Unilateral damage to frontal and parietal cortex in humans produces spatial neglect (or its milder form, extinction), a deficit in noticing and reacting to task-relevant objects in the region of space opposite to the affected hemisphere. Neglect has both sensory and motor manifestations and reflects a complex failure of linking sensory representations with conscious perception and overt behavior. The exact areas in the human brain whose damage produces neglect and the homologues of these areas in monkeys are not known with certainty. However, converging evidence suggests that in the monkey a parietal area, the lateral intraparietal area (LIP), and a frontal area, the frontal eye field (FEF), are critically important for spatial attention (Thompson, K. G. *et al.*, 2005; Gottlieb, J., 2007).

The LIP and FEF receive strong converging inputs from dorsal and ventral stream extrastriate areas and in turn send feedback to these areas. Consistent with these anatomical connections, LIP and FEF neurons have visual responses and circumscribed receptive fields similar to neurons in extrastriate areas. However, responses in LIP and FEF differ from those in extrastriate cortex in two important ways. First, LIP and FEF neurons are not strongly feature selective, but provide primarily information about the location of a selected object. Second, behavioral influences on neuronal activity in LIP and FEF are stronger and more multifaceted than those in extrastriate cortex.

Although they receive visual inputs, LIP and FEF neurons do not respond to most objects they encounter during viewing of complex visual scenes, but selectively encode the locations of objects that are physically conspicuous or that become relevant to an immediate goal. Conspicuous objects are encoded regardless of their specific visual features (e.g., their color or motion) and likewise, task-relevant objects are encoded regardless of the specific task for which they are relevant (for instance, whether they are designated as targets for a perceptual discrimination or for overt action). Thus, these areas appear to construct a relatively abstract salience representation that keeps track of a wide variety of objects that are likely to attract attention. Such integrated salience maps may be an efficient computational strategy for controlling the moment-by-moment allocation of attention.

The range of behavioral modulations in LIP and FEF is exceptionally broad and includes (but is probably not limited to) information about behavioral context or strategy, the expectation of reward and the prediction of the location and timing of task events. Modulations related to behavioral context filter visual inputs according the likelihood that these inputs are relevant to immediate behavior. For example, when monkeys search for a specific target in a cluttered display, FEF neurons respond strongest to the search target, more weakly to a distractor that is physically similar to the target and weakest to distractors that share the fewest features with the target. Similarly, LIP neurons respond more strongly to a salient visual transient if that transient is expected to mark the location of a search target than if it is not. The expectation of reward also modifies LIP and FEF responses so that targets expected to yield higher rewards elicit stronger responses than those expected to give lower payoffs. LIP and FEF neurons predict the expected location of a task-relevant target and LIP neurons are modulated

dynamically according to the monkeys' prediction of the timing of task events. Finally, prolonged training with a constant target can give rise to enduring modifications in visual sensitivity of attention-related areas in humans as well as monkeys, suggesting that connections between visual and attention-related areas are modifiable with experience.

These far-ranging behavioral effects suggest that the LIP and FEF interact with multiple behavioral systems including systems related to memory, temporal estimation, or reward estimation, and integrate information from these systems into a topographically organized signal of behavioral salience. This signal can guide the spatial allocation of attention based on a synthesis of immediate task demands. One way in which this signal is likely to act is by biasing the competition for neural responses in feature-selective visual areas (Reynolds, J. H. *et al.*, 2004). By virtue of feedback from LIP and FEF, task-relevant objects win the competition for neural representation in visual areas and consequently, are encoded and perceived more clearly relative to task-irrelevant distractors. Thus, attention-related areas can be seen as gateways that modulate the quality of visual perception according to a synthesis of immediate behavioral demands.

Simultaneously with their impact on visual processing attention-related areas are also instrumental in linking selected visual input with overt behavior (movement). Initially the LIP and FEF were thought to be specific for saccades – rapid eye movements with which primates scan their environment – and which are most closely related to visual attention. However, it is now recognized that these areas contribute to a wider array of actions including both ocular and skeletal movements and movements that are directly target or that are indirectly instructed by visual stimuli. The links between LIP and FEF and overt movement are bidirectional. In the forward direction, the salience representations in these areas influence motor planning by selecting objects relevant for action and facilitating motor orienting (e.g., with an eye movement) toward a task-relevant target. In the backward direction, salience responses in LIP and FEF are in turn influenced by motor planning. Thus, the preparation of an eye or limb movement become ingredients of salience – a means by which selection-for-perception can be coordinated with immediate motor output. The LIP and FEF therefore implement a complex, dynamic coordination between the perceptual selection of task-relevant targets and the planning of appropriate actions related to those targets.

2.19.4 Summary

Determining the salience, or potential importance, of various objects is one of the key operations of the brain. This determination is a multilevel process that depends on continuous feedforward and feedback interactions among multiple levels of visual representation. Elementary salient features of the visual input are extracted by hardwired circuitry at the earliest stages of visual processing. From the earliest stages, however, neural representations are also influenced by top-down information regarding the state of the observer. Top-down signals appear to be forged in higher-order visual association areas that bind sensory information with input from multiple behavioral, including motor, systems. Thus the construction of salience is an active process that depends on continuous interactions among sensory, behavioral and motor systems and may allow coherent, coordinated control of perception and action.

Glossary

classical receptive field (CRF) The CRF, also referred to as the minimum responsive field, is the receptive field mapped with a simple stimulus for which the sensory neuron is most selective. Stimuli placed outside the CRF alone usually do not evoke any response from the neuron, but when combined with other stimuli located in the CRF, they can significantly modulate neuronal responses, a phenomenon known as contextual modulation. The modulatory regions outside the CRF constitute the so-called nonclassical receptive field.

contextual modulation/interaction In perception, the term refers to various perceptual phenomena whereby the percept of a stimulus can be modified by the stimulus context within which the stimulus appears. In visual processing, it refers to an alteration of neuronal responses by contextual stimuli placed outside the classical receptive field.

cortical recruitment The reorganization of the cortical representation of the sensory surface, which can be induced by perceptual learning. Cortical recruitment usually results in an expansion of the cortical area representing the trained sensory surface by recruiting adjacent cortical areas representing untrained surfaces.

perceptual learning The unconscious improvement of perceptual ability with practice in simple discrimination and detection tasks.

top-down influences The modulation of perception or sensory processing by higher-order cognitive functions, like selective attention and expectation.

2.20.1 Introduction

Early investigation into the mechanisms of learning reflected the current philosophical trends. From the perspective of modern neuroscience, it is a commonsense notion that we assimilate all kinds of knowledge by interacting with the physical world. Until the seventeenth century, however, it was still a received doctrine that humans have native ideas stamped upon the mind from the very first being, and that we retrieve or derive our knowledge from an innate repository of ideas and principles. This idea was originally represented in the Platonic dialogues, which reflected the Socratic idea that learning is a recovery of lost knowledge that can be achieved by deductive reasoning (known as the Platonic doctrine of recollection). English philosopher John Locke attacked this notion in his essay (Locke, J., 1689), in which he likened the human mind to a blank slate, initially void of any ideas, and subsequently imprinted by ideas or knowledge obtained from an individual's experiences. Locke described perception as "the first and simplest idea we have from reflection," in which "the mind is, for the most part, only passive; and what it perceives, it cannot avoid perceiving." In his essay, Locke also reasoned that "the ideas we receive by sensation are often, in grown people, altered by the judgment, without our taking notice of it." Locke's concept here is a primitive form of the contemporary idea that our past experiences influence our perception.

Along similar lines, in the nineteenth century German physicist and physiologist Helmholtz H. (1866) interpreted perception as nothing more than our subjective ideas about external objects derived from the stimulation of our sensory organs; for Helmholtz, perception is a form of unconscious inference made by the mind. Given the psychical and creative nature of perception, Helmholtz observed that "the judgment of the senses may be modified by experience and by training derived under various circumstances, and may be adapted to the new conditions. Thus, persons may learn in some measure to utilize details of the sensation which otherwise would escape notice and not contribute to obtaining any idea of the object." This concept is exactly what we call perceptual learning today. By summarizing the writings of his contemporaries, American psychologist William James posed a theory of the neural basis of skill learning. James compared the formation of habits and skills to the plastic changes of materials, and attributed these behavioral changes to the plasticity of the brain (James, W., 1890). According to James, plasticity "means the possession of a structure weak enough to yield to an influence, but strong enough not to yield all at once." He stated that "our nervous system grows to the modes in which it has been exercised ... Habit diminishes the conscious attention with which our acts are performed ... The more of the details of our daily life we can hand over to the effortless custody of automatism, the more our higher powers of mind will be set free for their own proper work." A more contemporary representation of the idea of nervous system plasticity is found in the work of polish physiologist Jerzy Konorski (for a review on Konorski's work see Zielinski, K., 2006). Konorski distinguished plasticity from excitability as "an independent property of the functioning of higher nervous activity," "by virtue of which certain permanent functional transformations arise in particular systems of neurons as the result of appropriate stimuli or their combinations" (Konorski, J., 1948).

Among the experimental psychologists in the early twentieth century who contributed profoundly to our understanding of learning, Edward Thorndike (a student of James) was one of the most influential. By timing how fast cats were able to escape from a specially designed cage by trial-and-error, Thorndike proposed the law of effect governing behavioral learning, which states that "of several responses made to the same situation, those which are accompanied or closely followed by satisfaction to the animal will, other things being equal, be more firmly connected with the situation, so that, when it recurs, they will be more likely to recur" (Thorndike, E. L., 1911). Another important contribution by Thorndike to our understanding of the learning mechanisms comes from his studies on the transfer of learning. In the history of educational psychology there was a theory – the doctrine of formal discipline – which holds that the mind is like muscle: learning of a difficult disciplinary subject such as Latin can strengthen one's cognitive power in general and can therefore facilitate the learning of any other difficult subject. This doctrine was challenged by Thorndike's theory of identical elements, whereby the transfer of learning from one task to another can only occur insofar as the two tasks share common elements. This theory applies to very simple discrimination tasks, like judging the areas of geometric shapes (Thorndike, E. L. and Woodworth, R. S., 1901a; 1901b; 1901c). At about the same time, Russian physiologist Ivan Pavlov discovered a

different type of associative learning – classical conditioning (Pavlov, I. P., 1927). Based on the innate reflex that animals possess to certain stimuli (i.e., their unconditioned response to an unconditioned stimulus; e.g., salivation to favorite food), a new reflex (a conditioned response) can be formed in such a way that a neutral stimulus (conditioned stimulus, e.g., bell) that repeatedly precedes the unconditioned stimulus will eventually evoke the same response by itself. These earlier studies on associative learning inspired behaviorists like the American psychologist, Skinner B. F. (1938) and Konorski J. (1948) who made significant contributions to our understanding of instrumental learning (also known as operant conditioning, instrumental conditioning or type II conditioning), in which an animal's behavior is shaped by the consequences (e.g., reward and punishment) of past behavior, as stated by Thorndike's law of effect.

Learning is always associated with the formation and retention of certain forms of memory, which can be retrieved either consciously or unconsciously. The conscious form of memory, such as the recollection of previously seen objects and experienced events, is referred to as declarative memory or explicit memory, which is often acquired with a single exposure. The unconscious form of memory, which includes acquired habits and improved motor and perceptual skills, is called nondeclarative memory or implicit memory, which usually results from repeated experience. This classification of memory, which is based on the nature of memories and the involved brain structures (Figure 1), has been widely adopted throughout the study of learning and memory since the 1980s (for reviews see Schacter, D. L. *et al.*, 1993; Squire, L. R. *et al.*, 1993; Squire, L. R. and Zola, S. M., 1996; Squire, L. R., 2004; Squire, L. R. *et al.*, 2004). Whereas declarative memory is based in the medial temporal lobe, implicit memory can involve any area of the neocortex or cerebellum.

Much of what we know about learning and memory comes from studies on patients with specific damage to certain brain areas. The most famous case is patient HM, who has been used as a subject for 50 years (for review on HM see Corkin, S., 2002). HM's bilateral medial temporal lobes, including the hippocampal formation, were resected in an attempt to relieve his severe epilepsy (Scoville, W. B. and Milner, B., 1957). After the surgery, HM was no longer able to form any new explicit long-term memory, but the memories formed before the surgery were largely spared, despite partial retrograde amnesia. This suggests that the brain structures that store explicit memories are different from those that encode them. Moreover, despite HM's inability to form any long-term explicit memory, he is able to acquire and retain new perceptual and motor skills, even though he does not remember having practiced the tasks. The implication here is that the neural substrates for explicit and implicit memory are also distinct. Studies on amnesic patients suggest that different forms of memory are mediated by different brain structures.

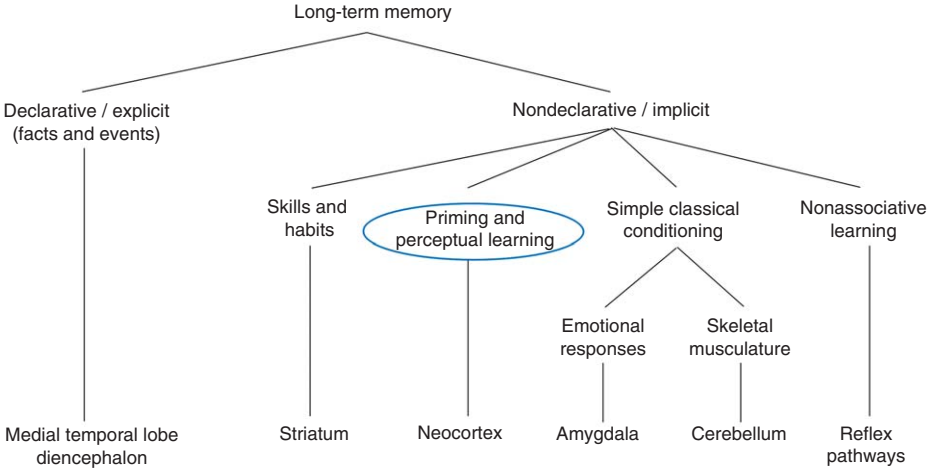

Figure 1 Classification of memory. Typical perceptual learning is a form of implicit memory whose encoding and retrieval do not reach conscious awareness. Reprinted from Neurobiol. Learn. Mem., 82, Squire, L. R., Memory systems of the brain: a brief history and current perspective, 171–177, Copyright 2004, with permission from Elsevier.

Perceptual learning is the unconscious acquisition of improved ability in simple discrimination and detection tasks with practice, and is an important form of implicit memory. It is a remarkable mechanism by which the brain adapts itself for better and more efficient processing of recurring stimuli. Some professionals, like artists, musicians, and gourmet chefs, rely on the extensive exercise of their sensory modalities to achieve extraordinary sensibility in vision, hearing, and taste. In a broad sense, perceptual learning is "any relatively permanent and consistent change in the perception of a stimulus array, following practice or experience with this array" (Gibson, E. J., 1963), or "any relatively long-lasting changes to an organism's perceptual system that improve its ability to respond to its environment and are caused by this environment" (Goldstone, R. L., 1998).

2.20.2 Psychophysical Studies on Perceptual Learning

In laboratory studies, perceptual learning is commonly seen as an improvement in performance after training on simple discrimination, detection, identification, and search tasks. This section will summarize some important findings from these psychophysical studies.

2.20.2.1 Time Course of Perceptual Learning

Perceptual learning causes a long-term change in perceptual skill. Subjects retain the learning effects derived from training on a perceptual task long after they stop practicing the task, for months or even years later (Ball, K. and Sekuler, R., 1982; Karni, A. and Sagi, D., 1993; Schoups, A. *et al.*, 1995; Crist, R. E. *et al.*, 1997). This enduring effect evolves with practice and time, showing different phases. A few tens of training trials suffice to improve a naïve subject's discrimination ability significantly in a vernier discrimination task (a visual task to discriminate the relative lateral offset of two end-to-end adjacent lines, Figure 2(c); Poggio, T. *et al.*, 1992; Fahle, M. *et al.*, 1995), indicating an early rapid phase in perceptual learning (see also Karni, A. and Sagi, D., 1993 for a fast learning phase in a texture detection task). The presence of a fast learning phase has also been demonstrated in an auditory frequency discrimination task after excluding the possible contribution of procedural learning (in which the subjects get used to the procedure of performing the task designed and instructed by the experimenters; Hawkey, D. J. C. *et al.*, 2004). Except for the quick learning phase within the initial test session, a subject's performance tends to stall within each daily training session

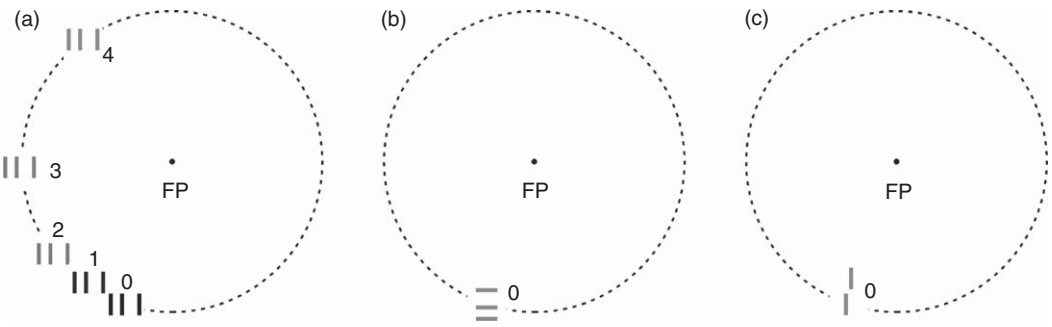

Figure 2 Specificity of perceptual learning in a three-line bisection discrimination task. The task stimulus used in this study consisted of three parallel lines. The two outer lines were fixed as a reference, while the central line was slightly displaced from the middle to either side. With fixation always at the fixation point (FP), the task was to determine whether the central line appeared closer to the left or to the right reference line. With a few weeks' training, the minimum displacement that was required for reliable discrimination of the positional offset of the middle line (i.e., the threshold for bisection discrimination) decreased by a factor of three on average. (a) The improved discrimination ability was restricted to the trained visual field location (labeled as position 0). When the same stimulus was moved away from the trained location (from 0 to 4) with the eccentricity kept constant, the training-resulted improvement gradually disappeared (denoted by a decrease in the darkness of lines). (b) Specificity of learning to stimulus orientation. At the trained location, a 90° rotation of the stimulus greatly diminished the learning effect. (c) Specificity of learning to stimulus context. Even if the task was to discriminate the lateral displacement of the same line at the same location, the learning effect did not transfer to a condition of new stimulus context, where a reference line was fixed at one end of the target line (this task is a form of the vernier task mentioned earlier). Adapted from Crist, R. E., Kapadia, M. K., Westheimer, G., and Gilbert, C. D. 1997. Perceptual learning of spatial localization: specificity for orientation, position, and context. J. Neurophysiol. 78, 2889–2894.

(Karni, A. and Sagi, D., 1993). Extensive training within the same day can even result in a decrease in performance, a phenomenon termed perceptual deterioration (Mednick, S. *et al.*, 2005). Nevertheless, relatively slow but steady improvement is evident across daily sessions (Karni, A. and Sagi, D., 1993; Schoups, A. *et al.*, 1995). This phase of gradual change lasts for many days before the subject's performance reaches an asymptote. Accumulated evidence shows that some rest (Karni, A. and Sagi, D., 1993) or sleep (Mednick, S. *et al.*, 2003; Atienza, M. *et al.*, 2004; Walker, M. P. *et al.*, 2005) after a training session is critical for the evolution and consolidation of improved discrimination ability. In fact, sleep may play an important role in memory formation and in cortical plasticity in general (for a recent review see Walker, M. P. and Stickgold, R., 2006). The requirement of a posttraining consolidation period is also supported by the finding that training on a new perceptual task immediately following a previous one without a sufficient delay interferences with the consolidation of the previously trained task (Seitzt, A. R. *et al.*, 2005).

2.20.2.2 Specificity of Perceptual Learning

Although perceptual learning occurs in virtually all kinds of perceptual tasks with repetitive exposure to the same stimulus and task conditions, the improved perceptual skill is usually highly specific to the conditions used for training. The specificity of perceptual learning is twofold. First, the improved perceptual skills obtained from training on different stimuli and tasks rarely interfere with each other (Ahissar, M. *et al.*, 1998; Seitzt, A. R. *et al.*, 2005). Second, there is little transfer of learning effect from a learned task and stimulus to a new task and stimulus. One has to undergo a new training process in order to improve under the changed conditions.

In visual perception, the commonly reported specificity of perceptual learning can be divided into four types. First, perceptual learning is restricted to the visual field location where the task stimulus is presented (Ball, K. and Sekuler, R., 1987; Berardi, N. and Fiorentini, A., 1987; Karni, A. and Sagi, D., 1991; Shiu, L. P. and Pashler, H., 1992; Fahle, M. *et al.*, 1995; Schoups, A. *et al.*, 1995; Ahissar, M. and Hochstein, S., 1996; Crist, R. E. *et al.*, 1997; Sigman, M. and Gilbert, C. D., 2000; Sowden, P. T. *et al.*, 2002). As the stimulus is moved away from the originally trained location, the observer's performance gradually regresses to the pretraining level (Crist, R. E. *et al.*, 1997; Figure 2(a)). Second, perceptual learning is specific to the stimulus used for training. Notably, a change in some simple attributes of the trained stimulus such as orientation (Ramachandran, V. S. and Braddick, O., 1973; Fiorentini, A. and Berardi, N., 1980; Schoups, A. *et al.*, 1995; Ahissar, M. and Hochstein, S., 1996; Crist, R. E. *et al.*, 1997; Sigman, M. and Gilbert, C. D., 2000; Figure 2(b)), moving direction (Ball, K. and Sekuler, R., 1982), spatial frequency (Fiorentini, A. and Berardi, N., 1980; Sowden, P. T. *et al.*, 2002; Yu, C. *et al.*, 2004), and size (Ahissar, M. and Hochstein, S., 1996), or even a change in stimulus context (Crist, R. E. *et al.*, 1997; Figure 2(c)), diminishes or abolishes the learning effect. Third, perceptual learning is specific to the particular perceptual task being practiced. Improved perceptual ability after training on one task does not usually generalize to other untrained tasks, even if the visual stimuli are very similar (Fahle, M. and Morgan, M., 1996; Fahle, M., 1997) or completely identical (Shiu, L. P. and Pashler, H., 1992; Ahissar, M. and Hochstein, S., 1993; Saffell, T. and Matthews, N., 2003). Since a perceptual task involves detecting or discriminating particular stimulus attributes, task-specificity is, in a sense, the specificity to the stimulus attributes that are relevant to the task. Learning to identify or discriminate one attribute has little effect on other tasks involving different attributes of the same stimulus. Finally, perceptual learning in some visual tasks is specific to the eye being trained. If only one eye is exposed to the task stimuli and the other eye is occluded, perceptual learning does not transfer to the untrained eye, as reported in a simple texture discrimination task (Karni, A. and Sagi, D., 1991), a luminance contrast detection task (Sowden, P. T. *et al.*, 2002), and a vernier discrimination task (Fahle, M., 2004).

While specificity is emphasized in most of the psychophysical studies, some have demonstrated partial or complete transfer of the learning effect under certain circumstances. It has been shown that the initial rapid learning phase is transferable between the two eyes, although some stimulus specificity remains (Karni, A. and Sagi, D., 1993; Fahle, M. *et al.*, 1995). Almost complete interocular transfer has been reported in an orientation discrimination task (Schoups, A. *et al.*, 1995), some acuity tasks (Beard, B. L. *et al.*, 1995), and pop-out detection tasks (Ahissar, M. and Hochstein, S., 1996; Schoups, A. A. and Orban, G. A., 1996). Some studies have shown that improvement in visual search tasks (involving the search for a unique target embedded in an array of similar distracters; Figure 3) transfers

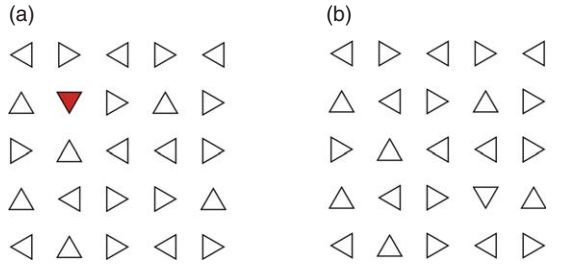

Figure 3 Learning effect on visual search. (a) An example of easy/parallel search. It is effortless to find a red target triangle pointing downward among an array of distracting triangles pointing to the other directions due to a salient difference between the target and distracters. (b) An example of difficult/serial search. To find the downward-pointing target triangle, a scrutiny of individual objects is required for naïve subjects. However, with a few days' practice, the serial/difficult search can be changed to parallel/easy search. Adapted from Sigman, M. and Gilbert, C. D. 2000. Learning to find a shape. Nat. Neurosci. 3, 264–269.

across different tasks, locations, and eyes, and is therefore less specific than the learning of simple discrimination tasks (Sireteanu, R. and Rettenbach, R., 1995; 2000; but see Ellison, A. and Walsh, V., 1998 and Sigman, M. and Gilbert, C. D., 2000 for some specificity in visual search tasks). Transfer of learning can also be manifested as an acceleration in learning speed when the stimulus parameters used for training are changed (Liu, Z. L. and Weinshall, D., 2000). In addition, learning an easy task can enable (Polat, U. and Sagi, D., 1994a) or facilitate (Liu, Z. L. and Weinshall, D., 2000) the learning of a difficult task. Perceptual learning can even transfer across sensory modalities: visual training on a shape discrimination task improves tactile discrimination ability of the same shapes (Hughes, B. *et al.*, 1990). It is still not clear under which circumstances the learned stimulus attributes or tasks are transferable. A recent study (Lu, Z. L. *et al.*, 2005) showed that the degree of interocular transfer increases with the amount of external noise added to the task stimuli, suggesting two distinct mechanisms in perceptual learning. In the presence of high external noise, a binocular mechanism of external noise exclusion, or perceptual template retuning, may be dominant, while in low external noise a monocular mechanism of stimulus enhancement may dominate. It has also been proposed that the degree of transfer depends on the task-relevant stimulus attributes and the difficulty of the perceptual task (Ahissar, M. and Hochstein, S., 1997; Liu, Z. L., 1999), and could reflect changes at different stages of information processing (Sireteanu, R. and Rettenbach, R., 1995; Ahissar, M. and Hochstein, S., 1997; Sireteanu, R. and Rettenbach, R., 2000; Ahissar, M. and Hochstein, S., 2004; for details see Section 2.20.4). But in any event, Thorndike's law of identical elements, which governs the generalization of learning, applies to perceptual learning as well (Thorndike, E. L. and Woodworth, R. S., 1901a).

2.20.2.3 Perceptual Learning and Contextual Interaction

Visual perception is usually affected by the global organization of the visual scene, namely, stimulus context. Early in the twentieth century Gestalt psychologists, typified by Max Wertheimer, proposed a set of laws governing perceptual organization. Rules like proximity, similarity and continuity determine how our visual system groups stimulus elements within a complex environment in order to properly identify individual objects (Wertheimer, M., 1923). Wertheimer also noticed that perceptual organization depends not only on the inner structure of stimulus context but also on past experience. The visual system tends to group those stimulus elements that have been previously associated with certain percepts (e.g., the well-known picture of hidden dalmatian dog created by R. C. James), suggesting an interaction between contextual influences and past experience.

That perceptual learning can modify contextual interactions is demonstrated by the observation that serial search can be changed into parallel search with training. Early studies of visual search suggested a dichotomy between parallel and serial search (Treisman, A. M. and Gelade, G., 1980; Julesz, B., 1981; Treisman, A. and Schmidt, H., 1982; Bergen, J. R. and Julesz, B., 1983). In parallel search, the target is distinct from its surrounding distracters in a certain conspicuous feature (e.g., color; Figure 3(a)). In this case, the target pops out by itself and little attention is required to locate the target. Therefore, the time needed to identify the unique target is independent of the number of distracters. In contrast, in serial search (such as the so-called conjunction search in which a combination of more than one feature is required to distinguish the target from the distracters), it is often necessary to serially direct one's attention to each object in the stimulus array. As a result, the search time is proportional to the number of distracters. Subsequent studies have revealed much more complex situations, suggesting that

parallel and serial search are simply two extremes of a continuum – an easy case and a difficult case – and that attentional state and training also affect the nature and speed of visual search. For example, some of the conjunction search tasks, which fall under the rubric of serial search by its original definition, can actually be performed in a parallel fashion (Nakayama, K. and Silverman, G. H., 1986). In contrast, for naive subjects, a parallel search task can be made serial if the subject's attention is taken away by a demanding task being performed simultaneously with the search task (Joseph, J. S. *et al.*, 1997). For experienced subjects, however, parallel search remains largely parallel regardless of the distracting task (Braun, J., 1998). A number of studies have also shown that a naïve observer's performance in some search tasks, being serial at the outset, becomes parallel with practice so that the hidden target pops out independently of the number of distracters (Figure 3(b); Sigman, M. and Gilbert, C. D., 2000; see also Wang, Q. *et al.*, 1994; Sireteanu, R. and Rettenbach, R., 1995; Ellison, A. and Walsh, V., 1998; Sireteanu, R. and Rettenbach, R., 2000; Yi, D. J. *et al.*, 2006). These studies suggest that perceptual learning can modify the interactions between contextual stimuli to facilitate the figure-ground segregation. This could be achieved by grouping a conjunction of features or a subset of visual elements into a single entity and by shifting the cortical representation of that entity from higher to lower areas (see Section 2.20.3.3.4).

Another example of the modification of contextual influences by perceptual learning is seen in collinear facilitation. Oriented stimulus elements, when arranged collinearly or smoothly along a continuous path, exhibit marked facilitatory interactions, as demonstrated in the phenomena of collinear brightness induction and contour saliency. In collinear brightness induction (Figure 4(a)), the contrast threshold for detecting the presence of a target drops significantly when the target is flanked by collinear stimuli (Dresp, B., 1993; Polat, U. and Sagi, D., 1993; 1994b; Kapadia, M. K. *et al.*, 1995; Polat, U. and Bonneh, Y., 2000). In contour saliency (Figure 4(b)), oriented stimulus elements that follow the Gestalt law of continuity are readily grouped together, forming a salient visual contour that pops out from its complex background (Field, D. J. *et al.*, 1993). This contour-linking process is known as contour integration. It has been shown that both collinear brightness induction and contour integration are significantly enhanced with training, with the enhancement

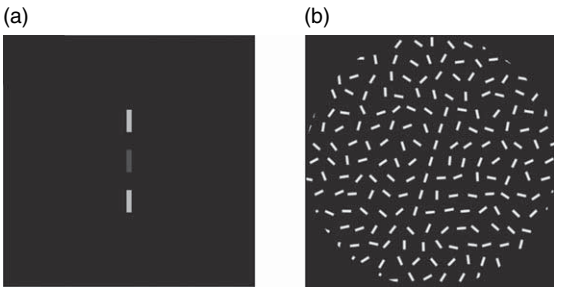

Figure 4 Collinear facilitation in visual perception is subject to perceptual learning. (a) Collinear brightness induction. The contrast threshold for detecting the presence of a target (the middle dim line) is significantly reduced in the presence of collinear flankers. (b) Contour integration. A stack of collinear lines embedded in a complex background are perceptually linked together, forming a salient contour. Perceptual learning strongly affects both collinear brightness induction and contour integration.

manifested both as an increase in the strength of collinear facilitation and as an increase in the effective spatial range within which the collinear interaction takes place (Polat, U. and Sagi, D., 1994a; Kovács, I. *et al.*, 1999; Li, W. and Gilbert, C. D., 2002;). In addition to pronounced learning effects in contour integration for both children and adults, contour integration ability improves with age in children, suggesting a late maturation of this perceptual ability (Kovács, I. *et al.*, 1999).

On the one hand, perceptual learning can modify contextual influences, but on the other hand, certain stimulus context could be helpful in learning to improve visual discrimination ability. It has been reported that contrast discrimination of an oriented target (a task to determine whether the target is brighter or dimmer than a reference) cannot be improved with training unless the training is conducted in the presence of collinear inducers (Adini, Y. *et al.*, 2002). This claim of context-enabled learning is currently under debate. Some recent studies have shown that contrast discrimination of an isolated target is learnable at different base (or reference) contrasts both in a blocked design (a single reference contrast is used within each block of trials; Yu, C. *et al.*, 2004) and in an interleaved design (different reference contrasts are mixed within the same block; Kuai, S. G. *et al.*, 2005). In the interleaved design, however, different reference contrasts must be presented in a fixed temporal order, as no learning effect takes place if they are randomly interleaved from trial to trial (Kuai, S. G. *et al.*, 2005). Here, a fixed

temporal pattern of stimulus presentation, namely temporal context, is critical in training on several mixed groups of stimuli, each of which has its own reference. These studies suggest that spatial and temporal contexts can be important for triggering the encoding mechanisms of perceptual learning.

2.20.2.4 Perceptual Learning and Top-Down Influences

Visual perception is generated by a combination of stimulus-driven bottom-up processes and behavior-driven top-down processes in the brain. A noticeable and extensively studied form of top-down influence is selective attention, which affords the attended objects or stimulus features more neuronal representation than the unattended ones.

Psychophysical studies reveal that attention is important not only for perception itself but also for perceptual learning. For the same visual stimulus, a subject's ability to discriminate a subtle change in a stimulus attribute can be improved only if the attribute is attended and used in the perceptual task (Shiu, L. P. and Pashler, H., 1992; Ahissar, M. and Hochstein, S., 1993; Saffell, T. and Matthews, N., 2003). The unattended attributes are unaffected in perception even though the subjects are repeatedly exposed to the same stimulus. For example, orientation and brightness are two different attributes of a straight line. When both attributes are altered from trial to trial, the discrimination ability of human subjects is improved only for the attended attribute (Shiu, L. P. and Pashler, H., 1992).

Despite the converging evidence that perceptual learning requires attention to the task-relevant stimulus attribute, some recent studies have shown that the discrimination of unattended and untrained stimuli is improvable under certain circumstances (Watanabe, T. *et al.*, 2001; 2002; Seitz, A. and Watanabe, T., 2003; Seitz, A. *et al.*, 2005). In these studies, the subjects' attentional resources were largely exhausted by performing a very demanding rapid-serial-visual-presentation (RSVP) task in the fovea, in which two white target letters had to be identified within a stream of rapidly displayed black distracter letters. Surrounding each letter was an array of dynamic random dots (DRDs) with subthreshold coherent motion (a small percentage of dots move in the same direction while the others move randomly). After extensive practice on the RSVP task while being passively exposed to the DRDs of subthreshold coherent motion, the subjects' ability to detect the coherent motion was significantly improved. Further investigation showed that the improvement only occurred for the coherent motion direction paired with the target letters, not for the other directions paired with the distracter letters (Seitz, A. R. and Watanabe, T., 2003; Seitz, A. *et al.*, 2005). That is, there is a strict temporal coupling between learning the unattended stimulus attribute (direction of coherent motion in DRDs) and the attended target. In this regard, attention is not completely dispensable in the subliminal learning. One possible explanation for the phenomenon is that attention is required for obtaining the reward signal that produces plasticity, but that this effect reinforces all stimuli that coincide with the attended stimulus (see Section 2.20.4). An enduring improvement in discrimination ability without training has been reported in somatosensory system. After extensive and passive stimulation of a small area on a finger tip, the subjects' spatial discrimination ability was improved for the stimulated skin area (Godde, B. *et al.*, 2000; Hodzic, A. *et al.*, 2004). In this case, the subjects had not been exposed to the task stimuli during the passive stimulation, so a possible role for top-down control was precluded. However, in this exceptional case, the enhancement in spatial discrimination ability was also accompanied by an impairment of temporal discrimination ability within the same skin area (Hodzic, A. *et al.*, 2004). As we will see later (see Section 2.20.3.3.1), prolonged passive stimulation incurs a reorganization of the somatosensory cortex, which is responsible for the change in tactile perception. This result pertains more to cortical plasticity than to typical modes of perceptual learning.

Another form of top-down influence on perceptual learning is the feedback that signals the observer's performance on the perceptual task. Although perceptual learning can take place without any external feedback signal (McKee, S. P. and Westheimer, G., 1978; Shiu, L. P. and Pashler, H., 1992; Fahle, M. *et al.*, 1995), strong effects of feedback have been reported. Correct feedback results in faster and more extensive improvement in performance than without it (Shiu, L. P. and Pashler, H., 1992; Herzog, M. H. and Fahle, M., 1997), whereas feedback uncorrelated with the subjects' responses prevents learning (Herzog, M. H. and Fahle, M., 1997). Moreover, there is no significant difference in the learning between the feedback given on a trial-by-trial basis or on a block-by-block basis (Shiu, L. P. and Pashler, H., 1992;

Herzog, M. H. and Fahle, M., 1997). These results indicate that nonattentional top-down influences also profoundly affect perceptual learning (Fahle, M., 2004).

While perceptual learning can be enabled or facilitated by top-down influences, the attentional mechanism itself is malleable and subject to learning. For example, perceptual learning results in a more effective attentional suppression of task-irrelevant stimuli, and this attentional learning is stimulus specific and long lasting (Vidnyanszk, Z. and Sohn, W., 2005). Moreover, perceptual learning ultimately leads to a release of the task from attentional control, resulting in automatization of the perceptual task (Shiffrin, R. M. and Schneider, W., 1977; Sigman, M. and Gilbert, C. D., 2000; see also Section 2.20.3.3.4).

2.20.2.5 Section Summary

The visual system can improve its performance on various perceptual tasks with training. For simple discrimination, detection and search tasks, the learned information is retained in the brain in the form of long-term implicit memory, which is usually specific to the trained task and the trained stimulus with little crosstalk. In addition to affecting the accuracy and speed of performing a task, perceptual learning, together with contextual modulation and top-down influences, strongly influences how we interpret visual stimuli. These modulatory factors also intimately interact with each other: perceptual learning can be affected by stimulus context and top-down control, and the mechanisms of contextual and attentional modulation themselves are subject to modification over the course of perceptual learning. These factors and their complex interactions necessarily determine the dynamic and creative nature of visual perception.

2.20.3 Cortical Mechanisms of Perceptual Learning

As mentioned in the introduction, the acquisition of explicit memory involves a rather unified memory system in the brain. This memory system is necessary neither for visual perception *per se* (for a recent study see Shrager, Y. *et al.*, 2006), nor for perceptual learning. For example, amnesic patients show learning effects that are comparable to normal observers in the vernier discrimination task (Fahle, M. and Daum, I., 2002). Several lines of evidence point to sensory cortices, including the primary sensory cortex, as the loci mediating perceptual learning.

2.20.3.1 Implications from Psychophysical Studies

Considered in conjunction with the functional organization of sensory systems, psychophysical findings offer insights into the cortical loci and mechanisms involved in perceptual learning. In the visual system, more than thirty cortical areas are associated with visual processing (Van Essen, D. C. *et al.*, 1992), and these areas are functionally specialized and hierarchically organized, forming partially segregated modules and pathways for processing different visual information (Van Essen, D. C. *et al.*, 1992; Zeki, S., 2001). The primary visual cortex (area V1) is the first stage of visual cortical processing, where neurons are selective for simple stimulus attributes like orientation and spatial frequency. In addition, the receptive fields (RFs) of V1 neurons are, on average, the smallest among all visual areas, and the visual inputs from the two eyes are still partially separate in V1. Ascending along the hierarchical pathway, response properties of neurons get more complex, the RFs get bigger, and the inputs from the two eyes become indistinguishable. Higher visual areas gain selectivity for more complex stimuli like faces, but loose spatial resolution and ocular identity. Therefore, given the specificity of perceptual learning to simple stimulus attributes, spatial location and the trained eye, the involvement of early visual areas in perceptual learning can be deduced from the functional organization of the visual system. For instance, the properties of V1 neurons – particularly their selectivity for simple stimulus parameters and their small RF sizes – make them suitable for learning tasks requiring high spatial resolution, like vernier and bisection discrimination. On the other hand, the dependence of perceptual learning on attention to specific stimulus attributes and tasks, together with the remarkable effects of feedback signals on learning, suggests the involvement of top-down control and an interaction between cortical areas. Moreover, the change from serial to parallel search with training and the release of perceptual task from attentional control – automatism of the task, in James' words (James, W., 1890) – suggest a shift of cortical

representation of the trained stimulus from higher to lower areas (Sigman, M. and Gilbert, C. D., 2000).

2.20.3.2 Implications from Lesion-Induced Cortical Plasticity

Another line of evidence suggesting the involvement of early sensory cortices in mediating perceptual learning comes from the accumulated findings that these cortical areas are highly plastic even in adults (fom reviews see Kaas, J. H. *et al.*, 1983; Weinberger, N. M., 1995; Edeline, J. M., 1999; Gilbert, C. D. *et al.*, 2001; see also Chapter Plasticity of Somatosensory Function during Learning, Disease and Injury).

In early postnatal development there are time windows, known as critical periods, during which the brain shows heightened plasticity and neural circuits are easily susceptible to modification by experience. The existence of critical periods was noticed by biologists nearly a century ago by studying the behavior of newborn animals. For example, Austrian ethologist Konrad Lorenz studied the phenomenon of imprinting, in which some birds (e.g., geese) have the tendency to treat the first moving object (e.g., Lorenz himself) they encounter after hatching as their parent and to attach themselves to this object. This imprinting behavior is restricted to a very short time period after hatching (Lorenz, K., 1935a; 1935b). Direct examination of cortical changes during the critical periods started from the 1960s. By suturing one eye of kittens for different periods of time after birth, Hubel D. H. and Wiesel T. N. observed a loss of responsiveness of V1 neurons to visual input from the sutured eye and determined the corresponding critical period for ocular dominance (Wiesel, T. N. and Hubel, D. H., 1963; Hubel, D. H. and Wiesel, T. N., 1970). They also anatomically demonstrated the changes that accompany monocular deprivation in the ocular dominance columns of juvenile monkeys (Hubel, D. H. *et al.*, 1977). So far a few clear critical periods in different sensory modalities and in different animal species have been well identified in terms of their timing, duration, and neural and molecular mechanisms (for a recent review see Hensch, T. K., 2004).

It was previously thought that the closure of the critical periods marks the maturation and stabilization of the brain, and that the neural connections and circuits should be fixed in adults. Nevertheless, since the late 1970s, pronounced reorganization of the central nervous system in adult animals has been observed after injury to the peripheral nervous system. For example, after severing the sciatic and saphenous nerves of adult cats, the spinal cord neurons on which the severed nerves used to terminate begin responding to adjacent intact nerves, thereby shifting their RFs (Devor, M. and Wall, P. D., 1978). A similar result has been observed in adult rats as well (Devor, M. and Wall, P. D., 1981). In the brain, striking reorganization of adult primary somatosensory cortex (area S1) has also been reported to follow deafferentation of the sensory input (Rasmusson, D. D., 1982; Merzenich, M. M. *et al.*, 1983a; 1983b; 1984; Calford, M. B. and Tweedale, R., 1988; Pons, T. P. *et al.*, 1991; Weiss, T. *et al.*, 2004). The cortical territory devoted to the representation of the deafferented body surface becomes responsive to adjacent body surfaces. Very similar plastic changes are also found in primary auditory cortex (area A1) of adult animals after restricted unilateral cochlear lesions (Robertson, D. and Irvine, D. R. F., 1989; Rajan, R. *et al.*, 1993), and in area V1 after retinal lesions (Gilbert, C. D. *et al.*, 1990; Kaas, J. H. *et al.*, 1990; Heinen, S. J. and Skavenski, A. A., 1991; Chino, Y. M. *et al.*, 1992; Gilbert, C. D. and Wiesel, T. N., 1992; Schmid, L. M. *et al.*, 1996; Eysel, U. T. *et al.*, 1999; Calford, M. B. *et al.*, 2000). A laser-induced retinal scotoma removes visual input to the corresponding retinotopic region in V1 and therefore silences neurons within that region, producing a cortical scotoma (Figure 5). However, several months following the retinal injury, the cortical scotoma shrinks: neurons within the cortical scotoma regain responsiveness by shifting their RFs outside the retinal scotoma. It has been shown that, rather than being derived from a rearrangement of thalamocortical afferents, the reorganization seen in V1 is cortically mediated, probably by the intrinsic horizontal connections in V1 (Darian-Smith, C. and Gilbert, C. D., 1995). The plasticity of early sensory cortices observed during recovery from injury has been suggested to serve as the neural basis of perceptual learning under normal physiological conditions.

2.20.3.3 Changes in Early Sensory Cortex Associated with Perceptual Learning

Since the 1990s, plastic changes associated with perceptual learning have also been demonstrated in early sensory cortices. In this section we will summarize these cortical changes into several categories, which to some extent depend on the nature of the perceptual tasks and could reflect different cortical

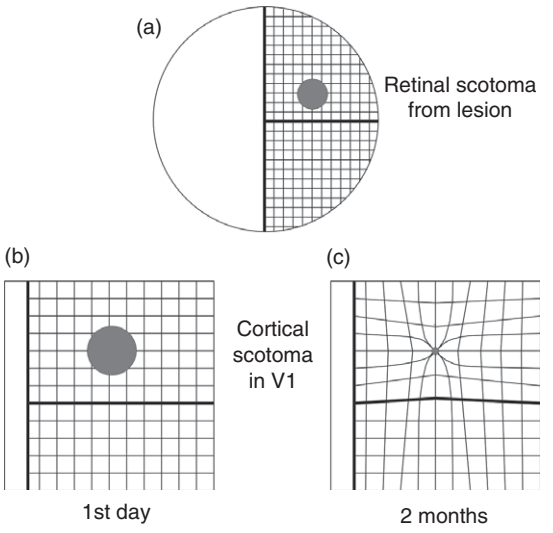

Figure 5 Reorganization of V1 after retinal lesion. A retinal scotoma caused by laser lesion (a, the small gray disc) creates a cortical scotoma in V1 (b). During recovery (c), neurons within the cortical scotoma regain responsiveness to visual input from the area surrounding the retinal scotoma. Adapted from Gilbert, C. D. 1992. Horizontal integration and cortical dynamics. Neuron 9, 1–13.

mechanisms of perceptual learning. We will describe in detail some cortical modifications that are well correlated with perceptual changes and can, therefore, account for perceptual learning.

2.20.3.3.1 Changes in cortical maps associated with discrimination training

The first piece of evidence that training on a discrimination task modifies early sensory cortex came from the observation of cortical recruitment, a process whereby the cortical area representing the trained sensory surface expands by recruiting the adjacent cortical areas previously representing the untrained surface. Intuitively, with the participation of a larger area of cortex and a proportionally greater number of neurons, better performance can be achieved in the discrimination task at the trained location due to probability summation: the probability of detecting a stimulus increases with the number of detectors/neurons, assuming that they are at least partially independent and that a subset is enough to signal the presence of the stimulus.

The primary sensory cortices are organized into orderly topographic maps to represent the sensory surfaces. These two-dimensional maps in S1, A1, and V1 are termed somatotopic, tonotopic and retinotopic maps, respectively. After training monkeys to perform a tactile frequency discrimination task using a small surface of one digit, remarkable reorganization of S1 has been observed, characterized by a significant increase in the size and complexity of the territory representing the trained skin area (Recanzone, G. H. *et al.*, 1992b; 1992c). Similarly, training on an acoustic frequency discrimination task results in up to a ninefold increase in cortical area representing the trained frequencies within A1 (Recanzone, G. H. *et al.*, 1993).

It is a matter of some debate whether the learning-associated cortical recruitment is actually responsible for the improved discrimination ability. There are several lines of evidence supporting the idea that it is, but some negative results have also been reported. Studies in monkey S1 (Recanzone, G. H. *et al.*, 1992c) and A1 (Recanzone, G. H. *et al.*, 1993) indicate that performing a tactile task while being passively stimulated by auditory stimuli mainly modifies S1 but not A1. Likewise, performing an auditory task while being passively stimulated by tactile stimuli mainly modifies A1 but not S1. Moreover, the reorganization is restricted to the cortical region representing the trained skin surface (S1) or the trained frequency range (A1). Therefore, cortical recruitment is specific to the sensory area where the task stimuli are processed. It has also been shown that increases in cortical representation are significantly correlated in A1 (Recanzone, G. H. *et al.*, 1993), and somewhat correlated in S1 (Recanzone, G. H. *et al.*, 1992c), with enhanced performance on the discrimination tasks. In a recent study (Polley, D. B. *et al.*, 2006), rats were trained to attend to either the frequency or the intensity attribute of an identical set of acoustic stimuli. Training on the frequency recognition task causes cortical recruitment in the frequency but not intensity domain of the topographic maps in A1 and higher auditory areas. In contrast, training on the intensity recognition task causes an increase in cortical sites that are sensitive to the target intensity but no change in the tonotopic maps. In both cases, cortical recruitment is correlated with improved performance. According to a study using the magnetic source imaging (MSI) technique (Braun, C. *et al.*, 2002), the topographic map in S1 is not only plastic, being modified by training on the discrimination task, but it is also rather dynamic, reorganizing according to different task requirements. Taken together, these findings suggest that the recruitment of specific cortical regions could be involved in solving specific discrimination tasks and

improving performance. While these studies emphasize the role of top-down influences in triggering the cortical recruitment, a recent human functional magnetic resonance imaging (fMRI) study has shown that prolonged passive tactile stimulation of a finger tip also significantly increases the cortical representation of the stimulated skin area in S1 and S2 (Hodzic, A. *et al.*, 2004). This augmentation is accompanied by a shift of the center of gravity of the reorganized cortical area, and the magnitude of the shift is strongly correlated with an improvement in spatial discrimination ability that is specific to the stimulated skin surface (Pleger, B. *et al.*, 2001; Hodzic, A. *et al.*, 2004).

Despite the evidence that cortical recruitment in S1 and A1 may account for perceptual learning, some issues remain unclear. In cat A1, a recent study (Brown, M. *et al.*, 2004) failed to show any cortical recruitment associated with training on an acoustic frequency discrimination task. Moreover, an expansion of cortical representation of a skin area in S1 or a frequency range in A1 occurs at the expense of the representation of adjacent skin areas or frequencies. If an increase in representation is responsible for the enhanced discrimination ability on the trained sensory surface, a decrease in representation would presumably result in impaired discrimination ability on the adjacent untrained sensory surface. Compelling evidence for such a phenomenon is still lacking, though it has been shown that training in a new skin area (Recanzone, G. H. *et al.*, 1992a) or in a new acoustic frequency range (Recanzone, G. H. *et al.*, 1993) degrades the learning effect for the previously trained skin area or frequency range. In addition, there is actually some evidence against a decrement in performance in untrained sensory surfaces (Brown, M. *et al.*, 2004). It is also worth pointing out that, in S1, the correlation between the area of cortical representation and the performance of the animal is not statistically significant (Recanzone, G. H. *et al.*, 1992c), but one would expect to see a close correlation if cortical recruitment mediates perceptual learning. Instead, a change in the temporal characteristics of S1 neuronal responses is suggested to be a more likely correlate with improvement in performance (Recanzone, G. H. *et al.*, 1992d; see Section 2.20.3.3.5). In the visual system, the lack of transfer between very similar tasks also argues against cortical recruitment. For example, in the bisection and vernier discrimination tasks mentioned earlier (Figure 2), the spatial offset of the same target line is discriminated in the same visual field location but in different stimulus contexts. If the improvement in one task is mediated by cortical recruitment, one would expect to see an improvement in the other task. Another argument against recruitment in visual learning is the absence of performance robbing from untrained visual field locations, which would be expected if the area of cortical representation correlates with performance. In fact, recent studies have shown that no change occurs in the retinotopic map in V1 after extensive training on bisection discrimination. However, changes do occur in V1 neuronal response properties that can account more for the context specificity of the learning and for the lack of transfer (Crist, R. E. *et al.*, 2001; Li, W. *et al.*, 2004b; see Section 2.20.3.3.2).

These mixed observations suggest that cortical recruitment is only one possible mechanism involved in perceptual learning. This mechanism could be specific to certain perceptual tasks in the somatosensory and auditory modalities, and it could be dependent on the stimulus and behavioral paradigms, or even on animal species (Brown, M. *et al.*, 2004). In addition to cortical recruitment, some changes in the basic properties of neurons within the reorganized cortical regions have been observed, such as an increase in the size and overlap of RFs (Recanzone, G. H. *et al.*, 1992c), a change in temporal response properties (Recanzone, G. H. *et al.*, 1992d), and a narrowing of tuning functions (Recanzone, G. H. *et al.*, 1993; Polley, D. B. *et al.*, 2006).

2.20.3.3.2 Changes in response properties of neurons associated with discrimination training

Response properties of visual neurons can be dynamically modified by a number of factors, notably stimulus context (for reviews see Allman, J. *et al.*, 1985; Gilbert, C. D., 1998; Albright, T. D. and Stoner, G. R., 2002; and Contextual Influences on Visual Processing: From Image-based to Scene-based Representations in this encyclopedia). The RFs of V1 neurons are usually mapped by moving a small bar of light in the visual field. The small responsive area determined in this way for a given cell is referred to as the cell's classical receptive field (CRF) or minimum responsive field. Within the last couple of decades, a large body of evidence has shown that V1 neuronal responses to a stimulus placed in the RF are profoundly modulated by contextual stimuli located outside the classically defined RF. Contextual modulation in V1 suggests that V1

neurons are involved in processing complex stimulus features in visual scenes, and in mediating many contextual interactions in visual perception (e.g., the collinear brightness induction and contour integration, Figure 4).

Recent studies have revealed that contextual influences in V1 can be strikingly altered by perceptual learning so as to fit the requirements of the perceptual task (Crist, R. E. *et al.*, 2001; Li, W. *et al.*, 2004b). V1 neuronal responses to a line positioned in the RF and orientated at the cell's preferred orientation are usually slightly inhibited by a second parallel line placed on either side of the RF (Kapadia, M. K. *et al.*, 2000). However, as shown by one study in which monkeys were trained on a three-line bisection discrimination task, this contextual influence in V1 can be greatly modified (Crist, R. E. *et al.*, 2001; Figure 6(a1) and 6(a2)). For a large proportion of cells, the contextual modulation of neuronal responses by the second line is profoundly increased during the performance of the bisection task. In a subset of these cells, weak contextual inhibition is even reversed to strong facilitation (Figure 6(a2)). The changes in magnitude and, in some cases, polarity, of contextual modulation are present only in the trained area, suggesting a task-specific modification of neuronal response properties. A more rigorous examination of task-specific contextual modulation was provided by a subsequent study (Li, W. *et al.*, 2004b). Monkeys were presented with an identical set of stimulus patterns on which they were trained to perform either a bisection or a vernier discrimination task (Figure 6(b1)). This study showed that V1 neuronal responses are strongly modulated by the stimulus attribute relevant to the immediate task, but that they are little affected by the other task-irrelevant attribute (Figure 6(b2)). Information theoretic analyses revealed that, compared with the task irrelevant condition, V1 neuronal responses carry significantly more information about the same stimulus attribute when it is used by the animal to solve the discrimination task. Taken together, these findings indicate that V1 neurons in the trained animals take on novel response properties related to the discrimination task, and that the exercise of these acquired response properties requires the same stimulus and behavior context as that during training. This cortical mechanism coincides with the specificity of perceptual learning. Interestingly, task-dependent modification of neuronal response properties has also been reported in auditory cortex. Neurons in ferret A1 respond differentially to identical tones used in tone detection versus frequency discrimination tasks (Fritz, J. B. *et al.*, 2005).

Not only can the complex responses properties of V1 neurons be modified by perceptual learning in a task-specific manner, but the basic tuning properties can also be changed by learning simple discrimination tasks. A study has reported an increase in orientation selectivity of V1 neurons after training monkeys in an orientation discrimination task (Schoups, A. *et al.*, 2001). Within the V1 region corresponding to the trained visual field location, a subgroup of neurons whose preferred orientations are between 12° and 20° away from the trained orientation show a significant increase in the slopes of their orientation tuning curves at the trained orientation (Figure 7). A steepening in the slope around the most sensitive orientations on the curves, which correspond to the trained orientation, would significantly enhance neuronal sensitivity to orientation differences at the trained orientation and thus improve orientation discrimination ability. This change in orientation tuning of V1 neurons is specific to the trained visual field location and trained orientation. A sharpening of the orientation tuning curve with training on orientation discrimination has also been reported in monkey V4 (a cortical area mainly involved in encoding visual information about color and form; Yang, T. M. and Maunsell, J. H. R., 2004).

Learning-associated cortical recruitment (see Section 2.20.3.3.1), as well as changes of neuronal tuning properties, requires attention to the stimulus attribute relevant to the task. This is consistent with the psychophysical finding that the encoding of the learned information is subject to top-down influences (see Section 2.20.2.4). Reorganized cortical maps in A1 and S1 are seen when the trained animals are anesthetized (Recanzone, G. H. *et al.*, 1992c; Recanzone, G. H. *et al.*, 1993; Polley, D. B. *et al.*, 2006), suggesting that these changes indeed take place in early sensory areas. However, in the visual system, neuronal response properties that emerge from learning the discrimination tasks are present only when the animal is executing the learned task. This suggests that top-down influences play a role in triggering recall of these acquired properties for the task at hand. One proposed neural mechanism is that (Li, W. *et al.*, 2004b), the information related to a given stimulus attribute is represented at the level of subsets of inputs to a cell, which are gated by the top-down signals via interactions between feedback connections from higher cortical areas and intrinsic connections within V1. This mechanism enables

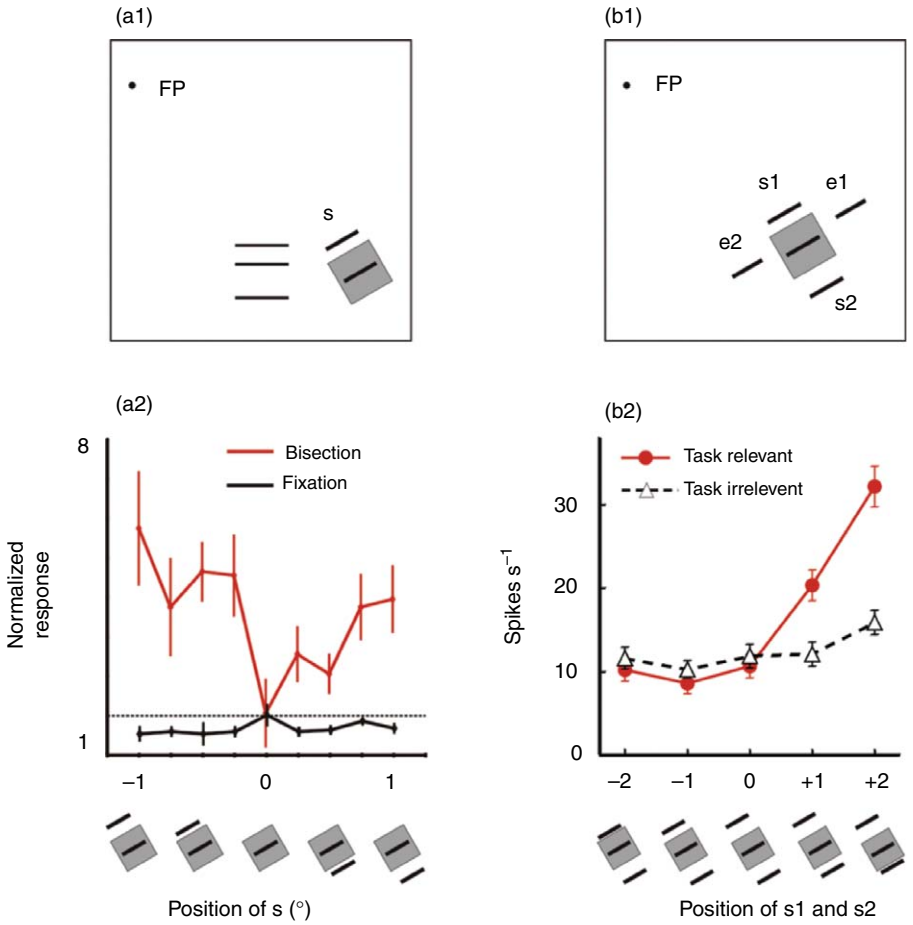

Figure 6 Perceptual learning modifies contextual interactions in V1 in a task-specific manner. (a1) Monkeys were trained to perform a three-line bisection discrimination task at a visual field location. The task stimuli consisted of three horizontal lines. Responses of single V1 neurons to another set of stimuli, the test stimuli, were recorded either when the animal did the trained bisection task or simply maintained its fixation at the fixation point (FP). The test stimuli consisted of two lines, an optimally oriented line fixed in the center of the RF (denoted by the small gray square), and a second parallel line (indicated by s) placed at different locations on either side of the RF (the cartoons at the bottom of (a2)). (a2) The normalized responses of a sample cell to the test stimuli are compared between the bisection and fixation task conditions. When the animal was performing the bisection discrimination task, the contextual modulation of neuronal responses by the second line was profoundly modified relative to the condition when the animal performed the fixation task. This change of contextual modulation was seen only in the trained area (for details see the text). (b1) Monkeys were trained to do two different discrimination tasks with identical stimulus patterns at the same visual field location. The stimuli consisted of five simultaneously presented lines: an optimally oriented line fixed in the RF center and flanked by four additional lines surrounding the RF. In different trials, the arrangement of the two side-flankers (s1, s2) was randomly assigned from a set of five different configurations (illustrated in the cartoons at the bottom of (b2) and labeled from -2 to $+2$). Each configuration differs from the others in the separation between the three side-by-side lines (in condition '0' the three lines were equidistant; in the other conditions either s1 or s2 was closer to the center line). In the same trials, the two end-flankers (e1, e2) were independently assigned a random configuration from a set of predefined arrangements, such that the end-flankers were collinear with each other but misaligned with the center line to either side. The animal was cued to perform either a bisection task based on the three side-by-side lines, or a vernier task based on the three end-to-end lines. (b2) One example of cells in response to the five-line stimuli under the two task conditions. Neuronal responses were examined as a function of the position of the two side-flankers s1 and s2 when the animal either performed the bisection task, in which s1 and s2 were task-relevant; or performed the vernier task, in which the same s1 and s2 were task-irrelevant. (a1,a2) Adapted from Crist, R. E., Li, W., and Gilbert, C. D. 2001. Learning to see: experience and attention in primary visual cortex. Nat. Neurosci. 4, 519–525. (b1,b2) From Li, W., Piech, V., and Gilbert, C. D. 2004b. Perceptual learning and top-down influences in primary visual cortex. Nat. Neurosci. 7, 651–657.

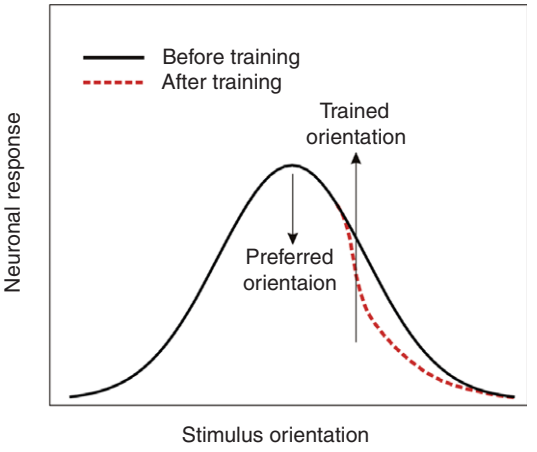

Figure 7 Increased orientation selectivity associated with training on an orientation discrimination task. The tuning curves shown here are only for schematic purpose. A significant change is observed for those neurons whose preferred orientations are at a certain distance from the trained orientation. The change is seen as an increase in the slope of orientation tuning curve on the flank that overlaps the trained orientation (Schoups, A. A. *et al.*, 2001; see also Teich, A. F. and Qian, N., 2003 for a model).

multiple learned attributes to be represented by the same cells without crosstalk, greatly expanding information processing capability in V1. Therefore, the top-down influences are critical in both encoding and retrieving the learned information.

2.20.3.3.3 Changes in neuronal responsiveness associated with discrimination and detection training

There is no reason *a priori* to expect that learning would always be associated with an increase in neural activity coming from a given cortical area. On the one hand, an increase in activity due to higher responses from individual neurons or from recruiting additional neurons could account for improvement because of an increase in the signal-to-noise ratio or probability summation. But on the other hand, a sharpening of tuning can also account for improvement in discrimination, yet this would mean that fewer cells would respond to the stimulus, leading to an overall decrease in neuronal responses.

Some discrimination tasks involve making a fine distinction between a target and a reference along a given stimulus dimension, like frequency, orientation or shape. It is not surprising, then, that training on such tasks would enhance neuronal selectivity for the task-related stimulus attributes (see Section 2.20.3.3.2). The changes in tuning properties are, in some cases, accompanied by changes in neuronal responsiveness. Some studies have reported increases in neuronal activity associated with discrimination learning. For example, over the course of learning a tone discrimination task in adult owl monkeys, an increase in sensitivity of A1 neurons to all frequencies is observed during the initial phase of improvement in performance. Subsequently, neuronal responses to the target stimuli are differentially intensified relative to the reference and nontarget stimuli (Blake, D. T. *et al.*, 2002). In monkey visual area V4, after training the animal on an orientation discrimination task, neurons with RFs overlapping the trained location show both narrower orientation tuning and stronger responses than neurons in the untrained hemisphere (Yang, T. M. and Maunsell, J. H. R., 2004). On the other hand, some studies have shown reversed results: a decrease of responsiveness in a subpopulation of neurons. A positron emission tomography (PET) study has shown decreased orientation-specific activity in early visual areas associated with orientation discrimination learning (Schiltz, C. *et al.*, 1999). Some studies have also shown both an increase and a decrease in neuronal responses in different subsets of V1 neurons, but both changes are associated with increased selectivity for the task stimuli (Crist, R. E. *et al.*, 2001; Li, W. *et al.*, 2004b). It is suggested that a change in neuronal responsiveness, with a corresponding change in the signal-to-noise ratio, is not directly related to the improvement in orientation discrimination, because a decreased signal-to-noise ratio in neuronal responses is observed at the trained orientation (Schoups, A. *et al.*, 2001). Therefore, the change of neuronal responsiveness in discrimination learning may be more closely related to the change in tuning properties, which better accounts for the improvement in discrimination ability (see Teich, A. F. and Qian, N., 2003 for a computational network simulation).

Unlike the discrimination tasks mentioned above, some perceptual tasks involve detection or identification of the presence or absence of a target, either in isolation near the detection threshold or within a noisy context. In this case, the intensity or signal-to-noise ratio of the target stimulus is more directly related to the task than any other stimulus attribute. Therefore, the responsiveness of neurons to the target is of key importance to solving the task. Depending on the nature of the target to be identified, activity in different visual areas is significantly

increased with training. It has been reported that an improvement in monkeys' performance on the detection of coherent motion of DRDs is predicted by an increase in neuronal activity in areas MT and MST (two cortical areas that are involved in processing motion signals; Zohary, E. *et al.*, 1994). Parallel results have been shown in visual area V4, which is at an intermediate stage along the hierarchical pathway for object recognition. Training monkeys to identify natural images degraded by noise specifically enhances V4 neuronal responses to those familiar and degraded pictures, and thus increases the amount of information that V4 neurons can extract from the stimuli (Rainer, G. *et al.*, 2004). In early visual areas, in particular in the most extensively studied area, V1, contextual modulation of neuronal responses is suitable for mediating center-surround interactions that are involved in many figure-ground detection tasks (for examples see Knierim, J. J. and Van Essen, D. C., 1992; Kapadia, M. K. *et al.*, 1995; Lamme, V. A., 1995; Rossi, A. F. *et al.*, 1996; Zipser, K. *et al.*, 1996; Nothdurft, H. C. *et al.*, 1999). Evidence from electrophysiological (Lee, T. S. *et al.*, 2002) and fMRI (Schwartz, S. *et al.*, 2002; Kourtzi, Z. *et al.*, 2005; Sigman, M. *et al.*, 2005) studies shows that training on detection of a target embedded in a background of noise or distracters significantly boosts activity in early visual areas. It has also been reported that the increased neuronal responses are correlated with the improvement in target detection (Lee, T. S. *et al.*, 2002). Training on target detection near the threshold and in the absence of any noise or distracter shows a similar effect (Furmanski, C. S. *et al.*, 2004). After training human subjects to detect a near-threshold grating patch, the fMRI signal in V1 for the trained orientation is significantly increased relative to the control orientation, and this change is correlated with the improvement in target detection.

In summary, the accumulated evidence indicates that an important mechanism of learning in target detection or identification near threshold or in the presence of external noise involves increasing the responsiveness of sensory neurons to the target and thus increasing the signal-to-noise ratio.

2.20.3.3.4 Shift of cortical representation of a learned stimulus with training on visual search

Visual search is a special kind of detection task in which the target is camouflaged in a background of similar distracters. In addition to engendering increased neuronal responsiveness in early cortical areas (see Section 2.20.3.3.3), learning to search for a particular shape results in a concomitant decrease in fMRI signals from higher visual areas involved in shape processing (Kourtzi, Z. *et al.*, 2005; Sigman, M. *et al.*, 2005) and from prefrontal and parietal areas involved in attentional control (Pollmann, S. and Maertens, M., 2005; Sigman, M. *et al.*, 2005; Figure 8). These studies suggest that another mechanism of perceptual learning involves a shift of cortical representation of the learned stimulus from higher to lower visual areas for more efficient and less effortful processing of the task stimulus. These findings also indicate that the attentional mechanism itself is pliable, being modified with training.

2.20.3.3.5 Changes in temporal properties of neuronal responses

The neural codes for sensory stimuli include not only the firing rates of neurons but also their temporal firing patterns, such as the synchrony of discharges across a population of neurons (for example see review Singer, W., 1999). It has been shown that temporal response properties of neurons can be modified by perceptual learning. For example, neuronal responses in monkey S1 become more coherent with training on tactile frequency discrimination. This change is highly predictive of the improved performance, and thus correlates better with learning than cortical recruitment does (Recanzone, G. H. *et al.*, 1992d). Similarly, after training rats to use the repetition rate of acoustic noise pulses to find food in a maze, with higher repetition rates indicating shorter distances between the animal and the food, A1 neuronal responses to high frequency noise pulses become stronger and more phase-locked to the stimuli (Bao, S. W. *et al.*, 2004). In the early visual areas (area 17, 18, and 21a) of the cat, gamma oscillations (an indication of response synchrony between neurons, see Singer, W., 1999) are increased for a behaviorally relevant stimulus on which the cats are trained, even if the animals are in a state of passive viewing and are not required to perform the associated task (Salazar, R. F. *et al.*, 2004). These studies suggest that the enhanced temporal response properties like increased synchrony and coherence of responses in a population of neurons can serve as another neural mechanism of perceptual learning.

2.20.3.4 Section Summary

In the search for the neural mechanisms of perceptual learning, it has been found that modifications in early

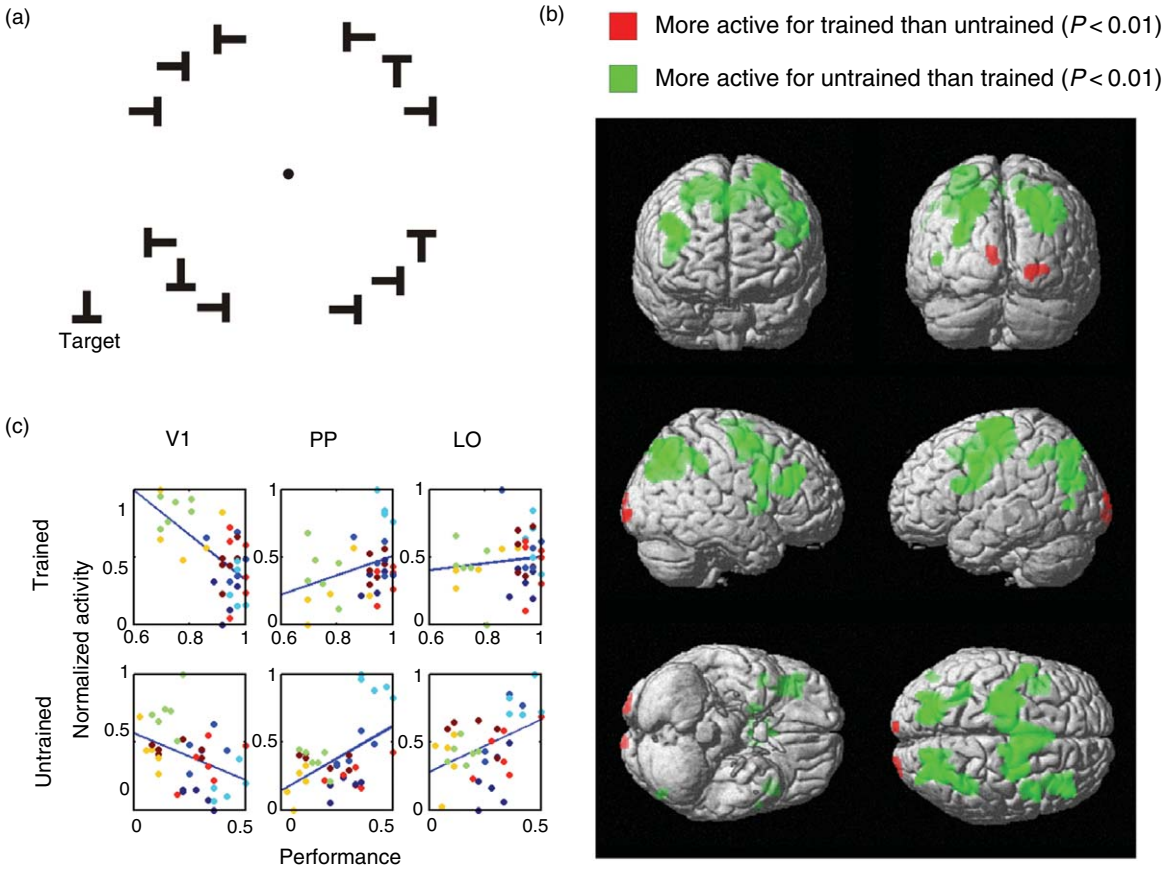

Figure 8 Shift of cortical representation of the learned shapes in training on visual search. (a) The task stimulus contained 12 Ts that were rotated by multiples of 90° and distributed in the four quadrants of the visual field. One rotated T was the target and the other Ts were distracters randomly pointing to the other three possible directions. The task was to report the quadrant within which the target T appeared. (b) Differential activation between the trained and untrained conditions. The first row shows the front and back views of the brain; the second row, the left and right hemispheres; the third row, the ventral and dorsal (bottom and top) views. The untrained condition was more active (shown in green) than the trained condition over an extended network that mainly involved the parietal and frontal cortices and lateral occipital cortices. The trained condition was more active (shown in red) than the untrained condition in the middle occipital cortex, corresponding to early visual areas in retinotopic cortex including V1. (c) Correlation between fMRI signals and behavioral performance for the three regions of interest – retinotopic cortex (RC), lateral occipital cortices (LO), and posterior parietal cortex (PP) – in the trained an untrained conditions. This analysis was based on the voxel that elicited the biggest difference between the trained and untrained conditions. At each voxel, the level of BOLD activity was calculated for each session and for each condition, and was correlated with the behavioral performance. For the trained condition, performance varied within the 60–100% range, and for the untrained condition, within the 0–50% range. RC activation is negatively correlated with behavioral performance, and the correlation becomes significantly stronger in the trained condition. LO and PP are positively correlated, and this correlation becomes substantially weaker in the trained condition. Reproduced from Sigman, M., Pan, H., Yang, Y. H., Stern, E., Silbersweig, D., and Gilbert, C. D. 2005. Top-down reorganization of activity in the visual pathway after learning a shape identification task. Neuron 46, 823–835.

sensory cortical areas are associated with training on various perceptual tasks. Some of these changes are well correlated with, and are therefore predictive of, the improvement in perception and the specificity of learning. These changes include an expansion of cortical representation; enhanced selectivity, responsiveness, and synchrony of neurons; and a shift of cortical representation of the learned stimuli. These plastic changes, which usually take place in a task-specific manner and are distributed across sensory cortices, are most likely involved in encoding the information about the learned stimuli, and thus

reflect the implicit memory formed during training. This is different from explicit memory, which involves a unified memory system located in the medial temporal lobe. Top-down influences specifically pertaining to the trained task may be required for both encoding and retrieving the learned information. This mechanism effectively prevents any potential interference between different perceptual tasks at the expense of the transfer of learning.

2.20.4 Theories and Models about Perceptual Learning

In addition to experimental studies, theoretical and computational approaches that endeavor to understand the possible neural circuitry can also provide insights into the mechanisms of perceptual learning. A few theories and models have been proposed, which emphasize different issues of perceptual learning, like different processes and stages of cortical processing.

Some of the computational models lay emphasis on plasticity at early stages of information processing. In a simple feedforward network model (Poggio, T. *et al.*, 1992), a task-specific module is synthesized based on simulated input from a few receptors on the retina that respond to vernier stimuli. This learning module improves its performance on vernier discrimination and reaches a hyperacuity level with only a few trials. Psychophysical observations are consistent with the simulated results in both the time course and orientation specificity. The algorithm can also be made to learn the hyperacuity task in the absence of feedback, with a corresponding decrease in learning speed, as is also observed with human subjects. A recurrent model has been proposed to explain V1 orientation selectivity (Benyishai, R. *et al.*, 1995; Douglas, R. J. *et al.*, 1995; Somers, D. C. *et al.*, 1995). Based on this model, a recent computational study has shown that the steepening of orientation tuning curves near the trained orientation (Figure 7) can be accounted for by slightly reducing the net excitatory connections to those cells tuned to the trained orientation (Teich, A. F. and Qian, N., 2003). This is consistent with some experimental observations (Schiltz, C. *et al.*, 1999; Schoups, A. *et al.*, 2001). In order to explain the context-enabled learning in contrast discrimination (see Section 2.20.2.3), a recurrent network model based on intrinsic inhibitory and excitatory interactions in V1 has been proposed (Adini, Y. *et al.*, 2002). Similarly, in another model (Hoshino, O., 2004), the strengths of lateral excitatory and inhibitory connections between neurons are modified according to a Hebbian learning rule (neuronal connections are strengthened if they fire together; for details see Section 2.20.5), and learning enhances the performance of the network by increasing the signal-to-noise ratio of neuronal activity. In a real situation of perceptual learning, due to small eye movements and fixation errors, there is a considerable amount of position variance in the visual signals, which presents a problem in solving hyperacuity tasks like bisection and vernier discrimination. However, as is shown by a modeling study (Zhaoping, L. *et al.*, 2003), a nonlinear recurrent network based on horizontal interactions can significantly outperform a feedforward network on the bisection task in the presence of positional uncertainty. The recurrent interactions in this network are highly specific to the stimulus parameters, and the recurrent connections in the model serve to modify the neural responses in a task-specific manner. Based on this model, the authors suggested that the fast phase in perceptual learning comes partly from learning the feedforward weights, and the slow learning phase results from learning the weights to implement the nonlinear transform.

By examining the training effect on visual discrimination tasks in the presence of different levels of external noise, a perceptual template model has been proposed (Dosher, B. A. and Lu, Z. L., 1998; 1999; Lu, Z. L. and Dosher, B. A., 2004; Lu, Z. L. *et al.*, 2005; Petrov, A. A. *et al.*, 2005). This model emphasizes two distinct mechanisms involved in perceptual learning – external noise exclusion (or perceptual template retuning) and stimulus enhancement. These studies also speculate that the improvement resulting from perceptual learning may simply reflect task-specific reweighting of the readout connections between early visual cortex and the decision stage, and thus perceptual learning does not necessarily involve modifications of early cortical areas. Similarly, by examining the effect of training on position discrimination at different noise levels, another study attributes the improvement to a retuning of the decision template (Li, R. W. *et al.*, 2004a). In the absence of external noise, some pooling models have made a similar claim that an improvement in performance does not need to change early sensory signals (Ghose, G. M. *et al.*, 2002). In contrast to the perceptual template model, by examining human performance

on identification of faces and textures embedded in noise, another study proposes the different view that perceptual learning entirely results from signal enhancement, not from noise reduction (Gold, J. *et al.*, 1999; for a debate see Lu, Z. L. and Dosher, B. A., 2004).

The central issue in the study of the neural basis of perceptual learning involves the loci in the brain where the plastic modifications occur. There is a considerable debate about whether the changes occur at early sensory cortices or higher cortical areas (for a review see Fahle, M., 2004). This discussion is also related to the specificity of perceptual learning and the role of top-down influences. A computational model (Herzog, M. H. and Fahle, M., 1998), which incorporates top-down mechanisms of internal evaluation of the performance and knowledge about the task, largely attributes the learning effect to a change in decision criteria. A reverse hierarchy theory (for a review see Ahissar, M. and Hochstein, S., 2004) suggests that learning-associated changes begin at higher levels in the visual pathway and progress backwards to lower levels. In particular, training on easy tasks modifies higher levels that are not sensitive to changes in simple stimulus parameters; therefore, the learning is transferable. In contrast, training on difficult tasks results in specific changes at lower levels, so the learning does not generalize.

A unified model has been proposed (Seitz, A. and Watanabe, T., 2005) in an attempt to reconcile task-irrelevant learning with task-relevant learning. According to this theoretical proposition, performing a task activates diffusive reinforcement signals, which interact not only with the task-relevant signals but also with those task-irrelevant signals that are temporally associated with the task stimulus. This theory compares task-irrelevant learning to classical conditioning in the sense that both phenomena rely on a temporal relationship between stimuli and reinforcers.

All the current models and theories have their own constraints, and can only address very limited aspects of perceptual learning (for a detailed comparison between different neural network models see review Tsodyks, M. and Gilbert, C., 2004). It will be important for a unified theory of perceptual learning to reconcile all the issues revealed by psychophysical and neurophysiological studies in the presence of complex behavioral and stimulus contexts.

2.20.5 Cellular and Molecular Basis

Significant strides have been made toward understanding the mechanisms of perceptual learning at the level of cortical plasticity. Another important direction of research has endeavored to relate perceptual learning to the changes seen at synaptic and molecular levels. This is particularly useful because at these levels all forms of cortical plasticity, including learning and memory, could share similar mechanisms, regardless of the different cortical structures or different experiences involved.

Cortical neurons are interconnected by synapses to construct intricate neural circuits, which are crucial determinants of brain functions like adaptive sensory processing. The synapses in the brain are formed at the cell bodies, dendritic shafts, dendritic spines, and the juxtaposition between specialized axonal swellings known as boutons. While synaptic stability is important for maintaining reliable neuronal functions like selectivity for primitive stimulus attributes, synapses must also be modifiable to endow neural circuits with adaptability to environmental changes. The dynamic and plastic nature of synaptic connections is seen as either an addition or elimination of synapses, or as a change in transmission at existing synapses.

More than a century ago, based on histological observations, Spanish histologist Santiago Ramón y Cajal proposed that changes in connections between neurons, which could be induced by cerebral gymnastics and which can take the forms of branching and strengthening, are responsible for our ability to learn (for a review see Jones, E. G., 1994). He also emphasized the integrative and plastic roles of pyramidal cells in neural circuitry because their axons provide long-range interarea and intra-area connections. Ramón y Cajal's propositions have been exemplified by modern experiments. It has been shown that lesion-induced cortical reorganization is associated with axonal sprouting in cat visual cortex (Darian-Smith, C. and Gilbert, C. D., 1994) and in monkey somatosensory cortex (Florence, S. L. *et al.*, 1998). Owing to the advances in two-photon microscopy, evidence from *in vivo* imaging on the same neurons at multiple time points indicates that, in the adult brain, the dendritic spines (Grutzendler, J. *et al.*, 2002; Trachtenberg, J. T. *et al.*, 2002; Holtmaat, A. J. G. D. *et al.*, 2005; Zuo, Y. *et al.*, 2005) and axonal boutons and branches (De Paola, V. *et al.*, 2006; Stettler, D. D. *et al.*, 2006) are rather dynamic, with

their elimination or formation occurring within days. These morphological changes have been shown to be associated with addition and subtraction of synapses (Trachtenberg, J. T. *et al.*, 2002; De Paola, V. *et al.*, 2006), and are most likely involved in mediating cortical plasticity. It has also been shown that a change in sensory experience increases the turnover rate of dendritic spines (Trachtenberg, J. T. *et al.*, 2002). In this study, a mouse's sensory experience was altered by trimming some of its whiskers. Reorganization of whisker representation in the barrel cortex is accompanied by an increase in transient spines and a concomitant decrease in stable spines – changes that are specific to the barrel cortex (Trachtenberg, J. T. *et al.*, 2002). Although similar changes have not yet been directly demonstrated over the course of perceptual learning, modern multiphoton microscopy may unveil the answer in the near future.

In addition to morphological changes, the transmission at existing synapses is also highly plastic, a phenomenon known as synaptic plasticity. In 1949, Canadian psychologist Hebb D. O. (1949) published his seminal theoretical postulate on the neural mechanism of learning, which states that "when an axon of cell A is near enough to excite a cell B and repeatedly or persistently takes part in firing it, some growth process or metabolic change takes place in one or both cells such that A's efficiency, as one of the cells firing B, is increased" (for a review on Hebb see Brown, R. E. and Milner, P. M., 2003). Since then, Hebb's idea has been contextualized in psychophysical, neurophysiological, and computational studies of learning, forming ideas like the Hebbian learning rule, the Hebbian neural network, the Hebbian synapse, and Hebbian synaptic plasticity. Synaptic plasticity is expressed in diverse forms and operates over a broad range of timescales (for a review see Abbott, L. F. and Regehr, W. G., 2004). The prevailing view is that long-term plastic changes of synaptic transmission are involved in learning and memory (for reviews see Martin, S. J. *et al.*, 2000; Morris, R. G. M., 2003; Lynch, M. A., 2004). Recent studies also emphasize the importance of pre- and postsynaptic spike timing in inducing synaptic plasticity (known as spike timing-dependent plasticity, see review Dan, Y. and Poo, M. M., 2004; Fox, K. and Wong, R. L., 2005). The contribution of short-term synaptic plasticity, however, is to enable complex dynamic information processing in neural circuits (for a review see Abbott, L. F. and Regehr, W. G., 2004).

One way to demonstrate a relationship between synaptic plasticity and perceptual learning is to show that the modulatory factors influencing synaptic plasticity also affect perceptual learning, as is done by a recent study (Dinse, H. R. *et al.*, 2003). This study employs the task-irrelevant learning paradigm (see Section 2.20.3.3.1) to show that inhibiting or facilitating synaptic plasticity has corresponding effects on perceptual learning. Recall that the passive stimulation of a finger tip improves spatial discrimination ability on the stimulated skin surface, and that this improvement is closely correlated with the cortical recruitment in S1. In human subjects, these changes can be completely eliminated by applying memantine, a drug that is known to block the *N*-methyl-D-aspartate (NMDA) receptors mediating Hebbian synaptic plasticity. In contrast, by applying a single dose of amphetamine (a central nervous system stimulant), the plastic effects are doubled.

Many studies have examined the neuromodulators that signal and control experience-dependent cortical plasticity. One of the neuromodulators noticeably involved in cortical reorganization and changes of RF properties is acetylcholine (ACh), which is released from the nucleus basalis (for reviews see Hasselmo, M. E., 1995; Weinberger, N. M., 1995; Edeline, J. M., 1999; Gu, Q., 2003; Weinberger, N. M., 2004; Wilson, D. A. *et al.*, 2004; Prakash, N. and Frostig, R. D., 2005; but see also Kamke, M. R. *et al.*, 2005). A large body of evidence has also shown that ACh is closely related to attentional mechanisms (for reviews see Everitt, B. J. and Robbins, T. W., 1997; Sarter, M. *et al.*, 2001; 2005). This coincidence may account for the close relationship between perceptual learning and top-down influences. One point of view is that the neuromodulators released while attentively performing a task serve as internal reinforcement (reward or feedback) signals; therefore, perceptual learning can take place even without any apparent reward or feedback, and can even occur for an unattended stimulus that coincides with the attended stimulus (Seitz, A. and Watanabe, T., 2005).

2.20.6 Concluding Remarks

This chapter outlines the current understanding of perceptual learning. It is evident that experience-dependent cortical plasticity is not restricted to early postnatal development or recovery from injury; it also serves as the neural basis of perceptual

learning throughout the life. Depending on the nature of the task stimuli, different cortical mechanisms are evoked to encode the learned information, which can be stored by modifying the functional properties and architecture of early sensory cortices. These changes usually take place in a task-specific fashion under top-down control. Similar top-down influences may also be required to retrieve the learned information relevant to a specific task. This provides an effective brain mechanism for avoiding interference across various perceptual tasks, as suggested by recent findings of task-specific plasticity in primary visual cortex (Crist, R. E. *et al.*, 2001; Li, W. *et al.*, 2004b).

It is worth noting that, for some complex visual tasks, in particular for those involving the recognition of complex objects and the association between different objects, learning is related to the formation of a more declarative form of memory (see Chapter High-level Visual Processing). In these cases, training on object discrimination results in modifications of neuronal response properties in monkey inferior temporal (IT) cortex (the last stage of the proposed object recognition pathway; Logothetis, N. K. *et al.*, 1995; Kobatake, E. *et al.*, 1998), and training on linking temporally associated objects creates neural codes in IT that represent long-term associative memory (Miyashita, Y., 1988; Sakai, K. and Miyashita, Y., 1991; Miyashita, Y., 1993; Miyashita, Y. and Hayashi, T., 2000; Messinger, A. *et al.*, 2005; Takeda, M. *et al.*, 2005). It has been suggested that both stimulus-driven bottom-up signals and behavior-driven top-down signals can trigger the retrieval of the associative information stored in IT (Miyashita, Y. and Hayashi, T., 2000).

It is also worth pointing out that, in spite of the diversity in the types of learning and the brain structures that are involved, different forms of learning and memory share some similar mechanisms. For example, the cortical mechanisms involved in perceptual learning are also found in motor learning (for reviews see Celnik, P. A. and Cohen, L. G., 2004; Paz, R. *et al.*, 2004). A recent study has shown that the encoding of implicit and explicit memory by exposure to the same stimuli shares the same processing factors, as the formation of both is intimately correlated (Turk-Browne, N. B. *et al.*, 2006). Given the similarities in neural mechanisms of different forms of learning and memory, understanding the neural basis of perceptual learning will have important implications for the study of learning and memory in general.

Glossary

composite effect Behavioral effect seen when the top half of one face and the bottom half of another are combined. When these halves are aligned while upright, observers appear to fuse the two halves and so find it difficult to perceive the identity of either half. In contrast, performance with inverted composites shows little effect of alignment.

face inversion effects Perception and memory of faces is much more affected by stimulus inversion than other stimulus classes.

face-selective activation In functional magnetic resonance imaging studies, face-selective activations are areas that show a higher response to faces than other stimuli. They are usually defined by comparing the response to faces to the response to objects or places.

fusiform face area (FFA) A region in the fusiform gyrus defined by its greater response to faces than other visual stimuli. It is usually stronger in the right hemisphere than the left.

occipital face area (OFA) A region in the occipital cortex which shows face-selective activation.

other race effect The decrement in performance often seen when observers attempt to recognize faces from other races.

prosopagnosia A condition characterized by severe face recognition deficits. Acquired prosopagnosia occurs due to brain damage whereas developmental prosopagnosia is the result of a developmental failure.

superior temporal sulcus (STS) This sulcus in the temporal lobe contains areas which show face-selective activations.

2.21.1 Introduction

Face processing is one of the most important functions of the human visual system, and it is essential for normal social functioning. Gaze flits from face to face in social situations as we effortlessly assess identity, emotional state, attractiveness, and locus of attention. The use of faces in identification cards and police sketches attest to their primacy for identity recognition, and portraiture and busts are highly valued because viewers feel they gain insight into the personalities of the depicted individuals. Nonhuman animals also show great sensitivity to facial information (Sackett, G. P., 1966; Burghardt, G., 1990; Waitt, C. *et al.*, 2003), and natural selection has had eons to sculpt human face-processing abilities. When face processing is severely impaired due to brain damage or developmental problems, people experience great social difficulties (Duchaine, B. and Nakayama, K., 2006).

Consistent with its importance, face processing has been the focus of extensive research using a wide variety of methods. This work has led to the development of a number of models of face processing (Bruce, V. and Young, A. W., 1986; Burton, A. M. *et al.*, 1999; Haxby, J. V. *et al.*, 2000), with the Bruce and Young model (1986) providing the key cognitive framework for face-processing studies through the last 20 years (see Figure 1). In it, lower-level processes

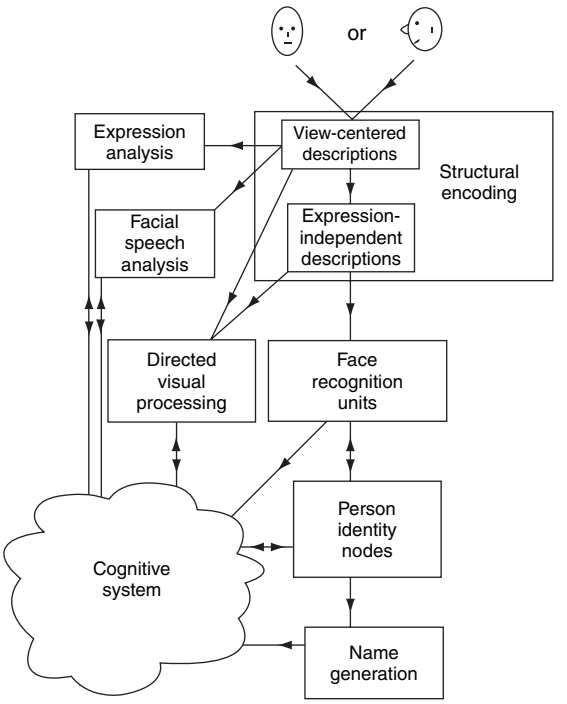

Figure 1 The Bruce and Young model of face processing. Reproduced with permission from the British Journal of Psychology © The British Psychological Society.

represent the facial image and later specialized modules carry out computations on different types of facial information such as identity, emotional expression, and mouth movements associated with speech. In this chapter, we review research investigating the processes involved in the recognition of facial identity, which is the best understood facet of face processing.

We first consider the nature of the perceptual/cognitive processes carrying out face recognition and discuss the special representation that is the basis of face recognition. Next, we review the neural basis of these computations, a research area which has seen an explosion of work in the last decade. We then discuss the neuropsychological impairments affecting these mechanisms and their implications for models of face recognition. We finish with a discussion of the development of face recognition mechanisms.

2.21.2 Cognitive Mechanisms

The idea that upright faces receive special processing has been supported by a number of cognitive experiments that reveal perceptual phenomena that are specific to faces. These studies suggest that faces are processed in a qualitatively different manner than objects or upside-down faces, and it is well accepted that they are represented holistically whereas nonfaces are processed in a more part-based manner. Although the term holistic has been defined differently in different papers (Maurer, D. *et al.*, 2002), it usually implies that faces are represented as one unit in which face parts are processed interactively rather than independently. Below we discuss several of the most robust cognitive effects indicative of holistic processing.

2.21.2.1 Inversion Effects

Aside from neuropsychological cases (see Section 2.21.4), cognitive studies provided the earliest and most convincing evidence that face processing engage specialized mechanisms. The first cognitive evidence came from a simple experimental procedure in which Yin R. (1969) asked subject to learn a set of faces and several sets of nonface objects (i.e., planes, houses, stick figures) to be recognize later. The stimuli were presented either upright or upside-down (inverted) during study and during test (see Figure 2). Although inversion of the stimuli resulted in lower recognition rates for all categories, the cost of inversion was much larger for faces. In fact, recognition rates for upright stimuli were best for faces whereas recognition rates for inverted stimuli were worst for faces. This robust phenomenon is typically referred to as the face inversion effect. It has been replicated numerous times since the original report and has been considered evidence that upright faces engage specialized mechanisms (e.g., Farah, M. J. *et al.*, 1998). Consequently, disproportionate inversion effects are sometimes used as a test to assess whether a given stimulus is processed by face-specific mechanisms or more general object mechanisms (Freire, A. *et al.*, 2000; Yovel, G. and Kanwisher, N., 2004; Duchaine, B. *et al.*, 2006).

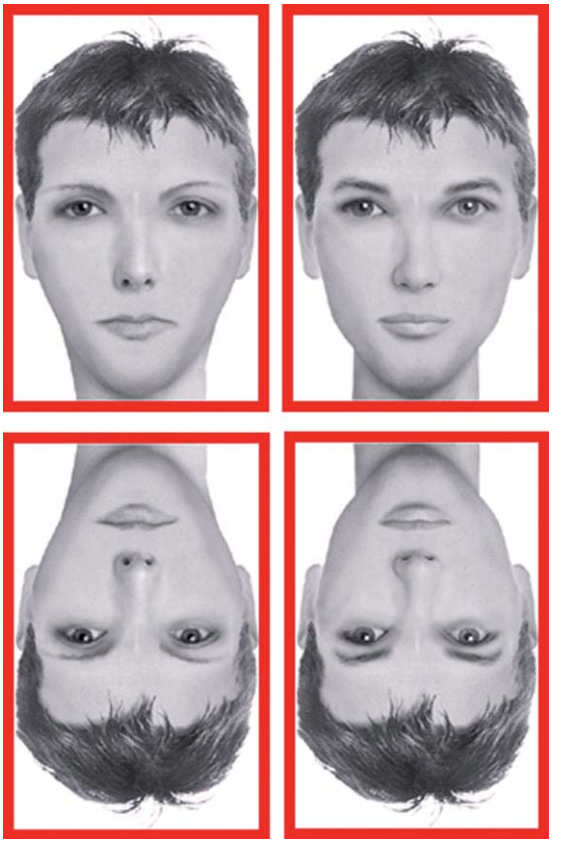

Figure 2 A pair of faces presented upright and inverted. Differences between the faces are much easier to perceive in the upright pair than the inverted pair.

2.21.2.2 Configural Processing

Later studies have tried to characterize the difference between upright and inverted face processing. Yin R. (1969) speculated that the difference involved a representation in which face configural information is better specified. Configural processing has referred

to two main phenomena: (1) holistic processing, that is, interactive processing of face parts and (2) sensitivity to spacing information (second-order relations; Maurer, D. *et al.*, 2002).

2.21.2.2.1 Holistic effects

Several paradigms demonstrate that face parts are processed interactively rather than independently.

2.21.2.2.1.(i) Composite effects In a seminal study that revealed holistic processing of upright faces, Young A. W. *et al.* (1987) presented subjects with composite faces created by combining the upper half of one famous face and the lower half of another famous face. The two halves were either aligned to create a coherent facial image or misaligned (see Figure 3). Subjects were asked to name either the upper or the lower half-face and ignore the other part. Response times were much longer for recognition of the one half of the face when it was aligned with the inconsistent half than when the halves were misaligned. Importantly, this effect was found for upright faces only. For inverted faces, subjects showed no difference in recognition time for aligned and misaligned faces. These findings suggest that halves are processed interactively when upright but independently when inverted. The composite face effect has also been demonstrated in perceptual matching tasks with unfamiliar faces in which subjects were asked to match the upper or lower halves of two sequentially presented faces (Hole, G., 1994; Le Grand, R. *et al.*, 2004). Thus, the two halves of the face are processed holistically at early perceptual stages and not only when they are stored for later recognition.

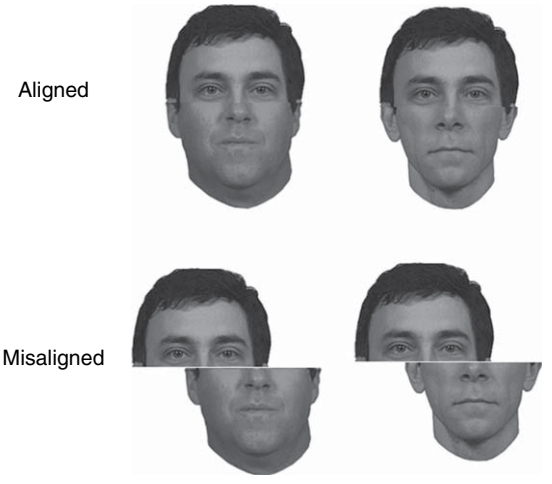

Figure 3 Composite faces created by combining the same top half with two different bottom halves. In tasks with composite faces, subjects find it much more difficult to determine whether the top halves are the same or different when they are aligned with the bottom halves than when they are misaligned. The difference between aligned and misaligned is much weaker or absent when the faces are inverted.

2.21.2.2.1.(ii) Part-whole effects Part-whole paradigms are another method that demonstrates that face parts are processed interactively for upright faces but not inverted faces. Tanaka J. W. and Farah M. J. (1993) presented subjects with a memory task in which subjects were asked to memorize a face and its name. During the test, a face part was presented to subjects either in isolation (part condition) or embedded in the original face (whole condition), and subjects decided whether the face part belonged to a given person (name). Performance was much better in the whole condition than the part condition (the part-whole effect). This effect was observed only for upright but not for inverted faces, upright houses, or inverted houses. In a follow-up study, Tanaka J. W. and Sengco J. A. (1997) showed that the precise location of the other face parts also interacts with recognition of individual parts. In particular, recognition of a face part was better when it was presented in the original face than in an original face in which the location of the other parts was altered. These findings suggest that face perception mechanisms encode both the shape of parts and their specific location (see also Section 2.21.2.2.2).

2.21.2.2.1.(iii) A whole face is more than the sum of its parts The composite face effect and the whole-part effect have examined recognition of face parts (e.g., a half-face, a face part) to determine how they are processed with relation to the rest of the face. Using a different paradigm, Yovel G. *et al.* (2005) estimated the extent to which face parts (i.e., right and left halves) are processed interactively or independently when subjects discriminate complete faces. In a face-matching task, facial stimuli were presented as either right half-faces, left half-faces, or complete faces. If the two halves are processed independently, the sum of accuracies for the right and left half-faces $[p(L) + p(R) - p(L)p(R)]$ will be comparable to the accuracy for complete faces. In contrast, if the two halves are processed interactively, performance with the complete faces will be better than the sum of the performance with the half-faces. Compared to this independence estimation, performance was higher for complete faces, which suggests interactive processing of the two half-faces. Like the composite and the

part-whole results, interactive processing of face parts was significantly reduced or absent for inverted faces.

2.21.2.2.2 Spacing effects

The experiments discussed above conceptualized configural processing as interactive processing of different parts or areas of the face. Configural processing has also been regarded as the sensitivity to the exact location of face parts or the spacing among the parts. Recent studies have tried to characterize what type of information is extracted by specialized face mechanisms. Studies of object recognition suggest that object processing is primarily part-based (Biederman, I., 1987; Braustein, M. L. *et al.*, 1989). In contrast, studies with faces have shown that we are very sensitive to minor dislocation of face parts (Haig, N. D., 1984) for upright but not inverted faces (Kemp, R., *et al* 1990). Thus, several studies have postulated that specialized face-processing mechanisms primarily extract information about the spacing among parts but not about the shape of the parts.

To assess this prediction directly, Freire A. *et al.* (2001) conducted a sequential same–different task with upright and inverted faces in which faces differed in one of two ways. On spacing pairs, faces differed only in the spacing among parts but the parts themselves were identical. Conversely, the part pairs consisted of faces in which the parts were different but the spacing of the parts remained the same (see Figure 4). The inversion effect was much larger for faces that differed only in spacing than for faces that differed only in parts. Based on the assumption that the size of the inversion effect reflects the extent to which information is extracted by specialized face-processing mechanisms, the authors concluded that these specialized mechanisms primarily extract information about the spacing but not the shape of parts (see also Leder, H. and Bruce, V., 2000; Le Grand, R. *et al.*, 2001; Mondloch, C. J. *et al.*, 2002).

However, the spacing and part tasks used by Freire A. *et al.* (2001) and Le Grand R. *et al.* (2001) were not matched for performance level (Yovel, G. and Kanwisher, N., 2004; Yovel, G., and Duchaine, B., 2006). In addition, the part manipulation was not limited to changes in the shape of parts, but these parts also differed in contrast and brightness. Thus, the absence of the inversion effect may reflect the operation of low-level visual mechanisms, which are

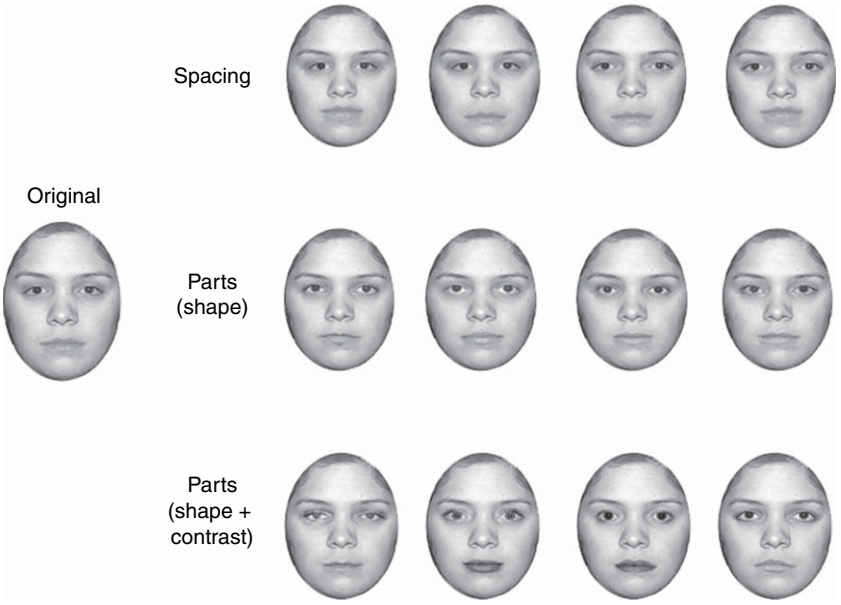

Figure 4 Faces from a same–different discrimination with three types of changes. The faces in the rows were created by modifying the original face on the left. In the spacing faces, the face parts are identical but the location of the eyes and mouth are varied. For the part (shape) faces, the locations of the features are identical but the face parts are different. The part (shape and contrast) faces also hold location constant but face parts differ in both shape and contrast. Rotate the figure to experience the inversion effect for the stimuli, differences are much more difficult to detect in the spacing and part (shape) variants than the part (shape and contrast) variants. Reproduced from Yovel, G., and Duchaine, B. 2006. Specialized face perception mechanisms extract both part and spacing information: evidence from developmental prosopagnosia. J. Cogn. Neurosci. 18, 580–593, with permission.

able to discriminate between the faces regardless of orientation based on color/contrast information. Indeed, several studies which matched performance for the spacing and part discriminations and which varied part shape but not contrast information found similar sized inversion effects for part and spacing discriminations (Riesenhuber, M. *et al.*, 2004; Yovel, G. and Kanwisher, N., 2004; Malcolm, G. *et al.*, 2005; Yovel, G. and Duchaine, B., 2006). Similar stimuli were presented in a fMRI study which examined the response of the face-selective fusiform regions during part and spacing discriminations with upright and inverted faces (Yovel, G. and Kanwisher, N., 2004). Face-selective regions showed a similar response to upright faces regardless of whether the discrimination involved parts or spacing and also showed a weaker response to inverted faces. Other evidence that face-specific mechanisms process parts and spacing comes from developmental prosopagnosia (Yovel, G., and Duchaine, B., 2006). These individuals have severe difficulties with both parts and spacing discriminations in faces despite normal performance on the same discriminations in houses. Furthermore, when face parts differ in contrast information, prosopagnosics were able to discriminate them as well as controls and control subjects showed no inversion effect for such face stimuli (Yovel, G. and Duchaine, B., 2006).

Finally, more direct evidence that spacing and parts are processed by shared rather than independent mechanisms was revealed in a study that employed an individual differences approach, in which the correlation across subjects between performance level for matching faces and house stimuli that differed in spacing or parts (Yovel, G. and Kanwisher, N., 2007). A significant positive correlation between performance for spacing and part discrimination was found only for upright faces. For inverted faces or houses, performance between the two tasks was not correlated. This suggests that face-processing mechanisms are special in that they represent information about spacing and parts, whereas general-object mechanisms processed the two types of information independently.

2.21.2.3 Are Faces Processed by Face-Specific or General-Purpose Configural Processing Mechanisms?

Whereas most researchers agree that faces are processed by holistic/configural mechanisms, the domain of these mechanisms is still debated. This mechanism could operate only on faces (Duchaine, B. *et al.*, 2006, Yovel, G. and Duchaine, B., 2006) or could process a wide variety of object classes (Levine, D. N. and Calvanio, R., 1989; Behrmann, M. *et al.*, 2005). Next we will review three nonface tasks that have been recently used to address this question.

2.21.2.3.1 The face-house spacing-part task

As mentioned above, several studies have shown that humans are very sensitive to the exact location of face parts and to the spacing among them (Freire A. *et al.*, 2000; Le Grand, R. *et al.*, 2001). These findings led researchers to suggest that face-processing mechanisms primarily extract spacing but not part based information. As we discussed above, recent studies have shown that both the spacing and the shape of parts are extracted by face-processing mechanisms, however, it is still not clear whether the ability to extract spacing information is limited to faces or is found also for nonface images. To answer this question Yovel G. and Kanwisher N. (2004) created house stimuli that, like the face stimuli, differed in the spacing among windows and doors or the shape of the windows and doors (part-task). These faces and houses were presented in a sequential matching task either upright or inverted. If configural-processing mechanisms are specific to faces, we should observe inversion effect for only faces but not houses. If, however, the mechanisms used with faces are also engaged in the processing of spacing information of non-faces, we should see an inversion effect in the house-spacing task. The results supported the face-specific hypothesis. Whereas faces yielded significant and equal sized inversion effects for both the spacing and the part task, there was no inversion effect for the house stimuli on either discrimination. These findings suggest that the specialized face-processing mechanism are specific to upright faces are not engaged by the processing of spacing information of non-faces.

2.21.2.3.2 Facelike processing of body stimuli

As mentioned above, the disproportionately large face inversion effect has been considered the hallmark of face-specific mechanisms. No other objects have produced a face-sized inversion effects until recently. Reed C. L. *et al.* (2003) have reported that human bodies yielded an inversion effect as large as they found with faces. In a perceptual matching task,

subjects were presented with upright or inverted pairs of faces and houses that differed in identity and whole bodies that differed in posture. Findings showed similar sized inversion effects for body posture and facial identity discriminations but no inversion effect for houses, though it is important to note that these effects (bodies = 5%; faces = 7%) were smaller than most face inversion effects (see Yovel, G. and Tambini, A., 2007 for a larger face than body inversion effect). In a more recent study, Reed C. L. *et al.* (2006) have examined whether the body inversion effect is specific for whole bodies or is also found for body parts. In one experiment, subjects matched whole bodies and houses or parts of bodies (leg, hand) and houses (window, door). Stimuli were presented either upright or inverted. Findings showed a larger inversion effect for whole bodies than whole houses and no inversion effect for body or house parts. In a second experiment, a comparison between whole bodies and faces to half bodies and half-faces revealed a similar significant inversion effect for all four conditions. These findings imply that, like upright faces, upright bodies are processed with special procedures.

Importantly, however, Reed's findings do not suggest that faces and bodies are mediated by the same configural mechanism. In fact, other studies suggest that they are mediated by distinct mechanisms. Yovel G. and Tambini A. (2007) found a larger inversion effect for faces and bodies and no correlation between performance on a face and body perception tasks (Yovel, G., and Tambini, A., 2007). Furthermore, recent functional magnetic resonance imaging (fMRI) findings revealed no overlap between face-selective and body-selective regions in the fusiform gyrus (Schwarzlose, R. F. *et al.*, 2005). Finally, developmental studies showed very early preference for the processing of upright than inverted faces (as early as the first day of life; Cassia, V. M., *et al.*, 2004), whereas the ability to discriminate between intact and jumbled body stimuli develops only during the second year of life (Slaughter, V. *et al.*, 2002). Thus, even if bodies are processed configurally, it appears likely that they are processed by configural mechanisms that are distinct from face configural mechanisms.

2.21.2.3.3 General expertise

A long-running debate in studies of face recognition concerns whether the putative face-specific effects are actually the hallmarks of expert processing (Diamond, R. and Carey, S., 1986; Tarr, M. J. and Gauthier, I., 2000; McKone, E., *et al.*, 2007). According to the expertise view, faces are processed in a qualitatively distinct manner but so are other object classes with which humans have substantial experience. Expert classes are claimed to be processed configurally, (Diamond, R. and Carey, S., 1986), and this predicts that experts will show the same effects that are seen for faces.

The seminal finding for the expertise view comes from Diamond and Carey's study of dog show judges (Diamond, R. and Carey, S., 1986). These dog experts, but not dog novices, showed face-sized inversion effects for the breed that they specialized in. To study the development of expertise in the laboratory, Gauthier and colleagues created the Greebles, a set of computer-generated objects designed to place similar demands on recognition mechanisms as faces. In training sessions, subjects learn individual Greeble names, their sex, or their family membership and are then tested on their recognition. A typical training regimen consists of eight sessions. Gauthier and colleagues have argued that Greeble training leads to behavioral results revealing configural/holistic effects (Gauthier, I. and Tarr, M. J., 1997; Gauthier, I. *et al.*, 1998; Gauthier, I. and Tarr, M. J., 2002) as well as neural effects similar to those seen in response to faces (Gauthier, I. *et al.*, 2000; Tarr, M. J. and Gauthier, I., 2000; Rossion, B. *et al.*, 2002).

New studies and close scrutiny of the evidence however reveals that the support for the expertise view of face recognition is weak (McKone, E. and Kanwisher, N., 2005; McKone, E., *et al.*, 2007). First, no findings with real world experts similar to the Diamond R. and Carey A. (1986) have been made in the intervening 20 years, and a recent study found that dog expertise did not show a larger inversion effect, part-whole effect, or composite effect than dog novices (Robbins, R. and McKone, E., 2007; for discussion, see McKone, E. and Robbins, R., 2007 and Gauthier, I. and Bukach, C., 2007). Despite many claims about Greeble effects, facelike effects do not emerge after Greeble training (Gauthier, I. and Tarr, M. J., 1997; Gauthier, I. *et al.*, 1998; Gauthier, I. and Tarr, M. J., 2002) and there has not even been a clear demonstration that Greeble training improves recognition of new Greebles (Gauthier, I. and Tarr, M. J., 1997). Recent fMRI work has found that expertise with objects increases responses in object-selective areas, not face-selective areas (Moore, C. D. *et al.*, 2006; Op de Beeck, H. *et al.*, 2006; Yue, X., *et al.*, 2006).

2.21.2.4 The Other Race Effect

The other race effect is a well-established, robust phenomenon in which individuals show better recognition for faces of their own race than faces of other races (e.g., Caucasian individuals recognize Caucasian faces better than Asian or black faces). As expected, it is not the race of the individual per se that determines the level of recognition of own and other race faces, but the type of faces that an individual has been exposed to throughout his life. For example, it has been shown that Caucasian individuals who frequently watch basketball games, which are dominated by black players, show good recognition of black faces (Li, J. C., *et al.*, unpublished). Interestingly, a study by MacLin O. H. and Malpass R. S. (2003) has shown that a racially ambiguous face will show another race effect when combined with other race hair but not when it is combined with own-race hair style. These findings suggest that when a face is categorized as another race face (based on non-facial features like hair), its facial features are not represented as well as when it is categorized as an own-race face. However, as discussed below, categorization is not the only factor that determines the way other race faces are represented.

Several studies have examined whether the poor recognition of other race faces may be associated with an absence of holistic processing for such faces. Earlier studies that examined the inversion effect for other-race relative to own-race faces have reported mixed results. Whereas some reported smaller inversion effect to other than own-race faces (Rhodes, G. *et al.*, 1989), other studies did not reveal similar findings (Valentine, T. and Bruce, V., 1986). One problem with studies that reported smaller inversion effect for other race faces is that they did not match performance level for the upright condition so the smaller inversion effect to other race faces may reflect scaling effect.

Studies that employed more direct measures of holistic processing, such as the abovementioned part-whole effect (Tanaka, J. W. *et al.*, 2004) or the composite face effect (Michel, C. *et al.*, 2006) revealed larger holistic effects for own than other race faces. Thus, the extensive exposure to own-race faces appears to be important for generating a holistic representation. It remains to be determined whether it is elevated holistic processing that allows better recognition of own-race faces or whether holistic representation and recognition abilities are two independent outcomes of extensive exposure.

The other race effect is typically attributed to perceptual mechanisms tuned to better represent same race faces than other race faces due to differential exposure. However, increased contact with other race faces has often failed to lessen the other race effect (reviewed in Levin, D., 2000). Levin D. (2000) suggests that other race effects are caused by selection of different facial features in same and other race faces. He proposes that individuating information is selected in same race faces whereas race specifying information is emphasized in representations of other race faces at the expense of individuating information. Consistent with this hypothesis and inconsistent with a simple perceptual tuning account, Levin D. (2000) found that subjects who showed the other race effect were better able to discriminate face race (e.g., which face is blacker?) than subjects who did not show the other race effect. Hence, for this task subjects with another race deficit better represented faces from other races than subjects who did not show an other face deficit. Levin argues that the differential selection is determined by higher-level cognitions such as whether an individual is concerned with the identity of a person or their race. This account is supported by recent findings showing that the other race deficit is eliminated by a positive mood induction (Johnson, K. J. and Fredrickson, B. L., 2005) and the effect of hair on faces with ambiguous race (MacLin, O. H. and Malpass, R. S., 2003).

2.21.3 Neural Basis of Face Recognition

Neurophysiological studies have reported ample evidence for specialized neural mechanism for faces. A robust face-selective response (a much higher response to faces than non-faces) has been reported with all relevant neurophysiological methods, including single-cell recordings, event-related potential (ERP), magnetencephalography (MEG), positron emission tomography (PET), and fMRI. Thus, the neural networks for face processing have been investigated with both high temporal resolution, which reveal face-selective neural response about 170–200 ms after stimulus onset, and with high-spatial resolution, which reveal face-selective regions in the occipitotemporal regions.

2.21.3.1 Single-Cell Recording

Single-cell recordings by Gross and colleagues and later in other laboratories during the 1970s and 1980s revealed cells in the superior temporal sulcus (STS) and inferior temporal cortex that showed highly specific responses to faces (Gross, C. G., *et al.*, 1972; for review see Gross, C. G., 2005). Examination of the response properties of these face cells has revealed a variety of response properties. The response of some cells was invariant to the size and position of the face image (Perrett, D. I. *et al.*, 1982). Others were view-selective with different cells responding to different views (e.g., Perrett, D. I. *et al.*, 1985; 1992), whereas others responded to all views (Desimone, R. *et al.*, 1984). Manipulations of the intactness of the face image, such as covering or scrambling face parts weakened the response of some of the cells, which responded vigorously only to intact faces (Perrett, D. I. *et al.*, 1982; Desimone, R. *et al.*, 1984). Head rotation and face inversion resulted in increased latencies of some of the cells (Perrett, D. I. *et al.*, 1998). Recent fMRI studies with monkeys, which will be discussed later, revealed activations that are consistent with this early single-cell recording work. Furthermore, studies with humans have also reported neural responses that are highly selective to faces as detailed below.

2.21.3.2 Event-Related Potentials

During the mid- and late 1990s, electrophysiological studies with humans revealed a robust and reliable selective response to faces. In particular, ERP studies measure a scalp electrical response that is time-locked to a given stimulus. ERP studies that presented subjects with various images such as faces, objects, or animals revealed a negative bilateral component that peaked 170 ms after stimulus onset (N170) at occipital-temporal electrodes that was much larger to faces than non-face images and larger over the right than the left temporal electrodes (Eimer, M., 1998; Bentin, S. *et al.*, 1996; see Figure 5). Further studies have shown that the N170 is influenced by variations in the intactness of the face image. Scrambling, contrast reversal, and orientation inversion elicit an N170 of slightly larger amplitude and a small but significant delay (George, N. *et al.*, 1996). Furthermore, the N170 shows a much larger response to presentation of eyes only (Bentin, S. *et al.*, 1996), which led some researchers to suggest that it is generated by the STS, which is sensitive to social aspects of facial information such as gaze (Hoffman, E. A. and Haxby, J. V., 2000; Hooker, C. I. *et al.*, 2003).

The question of whether the N170 encodes only the structure of the face image or also face identity information is still debated. Earlier studies found no difference between the response to familiar and unfamiliar faces and concluded that the N170 is not sensitive to face identity (Bentin, S. and Deouell, L. Y., 2000). However, studies that examined repetition effects (i.e., different response to second presentation of the same stimulus) to repeated presentation of unfamiliar faces reported mixed results. Whereas some studies found lower amplitude for repeated

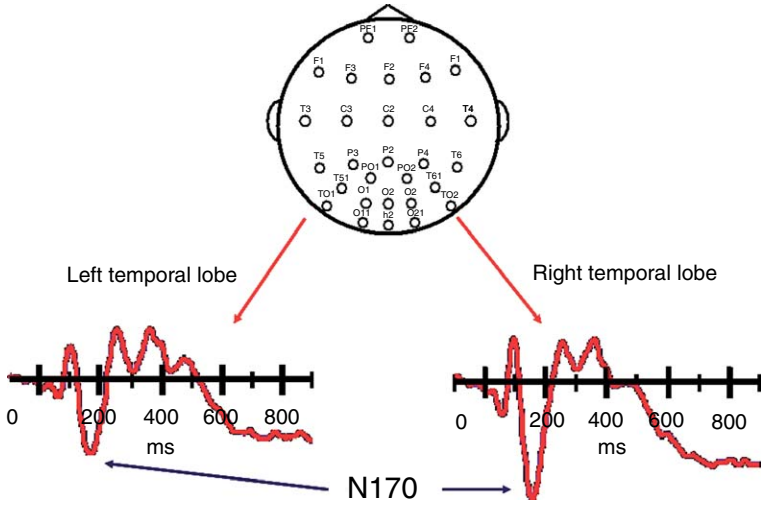

Figure 5 Schematic showing the sensors producing the largest N170 in event-related potential studies. The N170 to faces is much larger than that seen in response to other categories, and as in the figure, it is right lateralized.

presentation of the same individual face (Campanella, S. *et al.*, 2000; Itier, R. J., and Taylor, M. J., 2004a; Jacques, C., and Rossion, B., 2004), others reported no modulation by repetition (e.g., Yovel, G. *et al.*, 2003). The discrepancy between findings may be due to differences in the lag between repetitions and the number of repeated presentation. Thus, these studies suggest that, at least under some conditions (familiarization (Campanella, S. *et al.*, 2000), several repetitions (Itier, R. J., and Taylor, M. J., 2004a), or short delays (Jacques, C., and Rossion, B., 2004)), the N170 is sensitive to face identity information.

Another face-selective ERP component, the vertex positive potential (VPP), is observed at the same latency as the N170 but is maximal at a central electrode (Jeffreys, D. A., and Tukmachi, E. S., 1992). Like the N170, the VPP is delayed by face inversion or contrast inversion but it is not affected by familiarity and some studies have tried to assess the extent to which the VPP reflects the same neural source as the N170. In a recent systematic investigation, Joyce C. and Rossion B. (2005) have examined the effect of the location of the reference electrode and experimental manipulations on the VPP and N170 and found that the manipulated factors had similar effects on both components. Taking together with results of source localization, they concluded that the VPP and N170 are generated by the same source.

2.21.3.3 Magnetoencephalography Studies

MEG studies, which measure the magnetic fields produced by electrical activity in the brain, have revealed a similar face-selective negative component that also appears 170 ms after stimulus onset at lateral posterior electrodes. In addition, Liu J. *et al.* (2002) reported an earlier face-selective component that appeared 100 ms after stimulus onset (M100). Similar to the N170, the M100 and the M170 are delayed for orientation-inverted faces (Liu, J. *et al.*, 2000) and contrast-inverted faces (Itier, R. J. *et al.*, 2006); however, in contrast to the N170 these have no effect on amplitude. Another difference between the ERP and the MEG face-selective components is that the amplitude of the M170 is similar over the two hemispheres, whereas the N170 is larger over the right hemisphere (Bentin, S. *et al.*, 1996; Henson, R. N. *et al.*, 2002; Yovel, G. *et al.*, 2003).

In an elegant study, Liu J. *et al.* (2002) examined the role of the M100 and M170 in face categorization (discrimination between a face and a house) and face identification (discrimination between two faces). In a behavioral study, the authors determined the level of noise that allows categorization and the level that allows recognition for each subject. These at-threshold stimuli were presented to the subjects during MEG recordings and the evoked responses were classified based on subjects' success or failure in a face/house categorization and in their ability to recognize particular faces and houses. Results clearly showed that the M100 was sensitive to success in face categorization but not face identification. The M170 was sensitive to success in face categorization and identification. These components were not sensitive to performance for house stimuli or for stimuli for which subjects had expertise (Xu, Y. *et al.*, 2005). Finally, a recent study that examined category repetition effects for faces and houses (i.e., reduced amplitude for a second presentation of the same category) revealed that the M170 shows repetition effects (lower response for repetition of face–face than face–house) only when the delay between the first and second presentation is shorter than 400 ms (Harris, A. and Nakayama, K., 2007). These findings suggest that the M170 is generated by very early stages of face processing in which the facial image is not maintained for long durations.

In summary, although the N170 and M170 share some similar features in their response to faces, differences exist. It is unclear whether these reflect differences between electrical and magnetic responses from the same source or different sources (Itier, R. J. *et al.*, 2006).

2.21.3.4 Intracranial Recording of Neural Responses

Studies with epileptic patients enable intracranial recording of electrophysiological responses in humans. Such recording, which provides both high temporal and spatial resolution of the neural response, has been applied with face stimuli both with macroelectrodes which allow recording of evoked responses over the cortex and microelectrodes which allow recording of single cells. In an extensive investigation of intracranial ERPs of 98 epileptic patients, McCarthy G. *et al.* (1999) found a face-selective negative ERP component that appeared 200 ms after stimulus onset (N200). The face-selective component was maximal over certain patches in the ventral occipitotemporal cortex. Consistent with the N170 laterality, such patches were larger over the right than left hemisphere.

Investigation of the properties of this component showed invariance to size, color, and blurring. The response was largest for full faces and weaker for isolated face parts (eyes, nose, mouth), which evoked strong responses in other nearby locations. Similar to single-cell recordings, face rotation altered the amplitude of the N200, which was lowest for profile views (McCarthy, G. *et al.*, 1999). Like the N170, the N200 was not sensitive to face familiarity or to semantic priming and was therefore considered a neural correlates of initial structural encoding of face information prior to extraction of identity information (Puce, A. *et al.*, 1999).

In another study, single-cell recordings in epileptic patients conducted in the medial temporal lobe revealed neurons that responded selectively to images of faces, scenes, or objects (Kreiman, G. *et al.*, 2000). Further investigation of these cells (Quigora *et al.*, 2005) revealed that some of these cells respond selectively to certain individual familiar faces (e.g., Jennifer Aniston, Halle Barry) or familiar locations (Sydney Opera House). Furthermore, these cells are remarkably invariant to radical image variations (e.g., rotation, lighting, coloring) and in some cases were activated by letter strings of the name of the individual face/place. These findings suggest that some of these cells, which are anterior to the location of the N200 or the N170, are not purely visual but represent some abstract concept of individuals.

2.21.3.5 Functional Magnetic Resonance Imaging Studies of Face Recognition

2.21.3.5.1 Face-selective functional magnetic resonance imaging regions

Selective activation to faces in temporal occipital regions was first reported in PET studies. Sergent J. (1991) reported right lateralized fusiform activation to faces relative to scrambled faces. However, the first systematic investigations of brain regions that selectively respond to faces were fMRI studies by Kanwisher N. *et al.* (1997) and McCarthy G. *et al.* (1997). These studies revealed regions that elicited a much higher fMRI response to faces than non-face stimuli in the fusiform gyrus (see Figure 6). Kanwisher N. and colleagues (1997) referred to these face-selective regions as the fusiform face area (FFA). The FFA was larger over the right than the left hemisphere and showed a very selective response to any stimulus that contained facial information, including upright Mooney faces, animal faces, cartoon faces, and inverted faces (Tong, F. *et al.*, 2000),

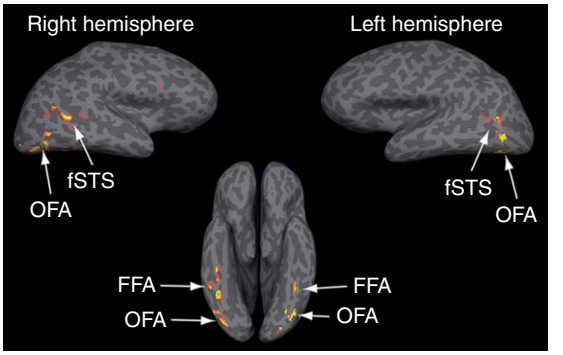

Figure 6 Inflated brain showing three face-selective areas: fusiform face area (FFA), occipital face area (OFA), and the face selective area in the posterior part of the superior temporal sulcus (fSTS).

but not to any objects or other body parts such as hands and feet (see also Schwarzlose, R. F. *et al.*, 2005). The FFA also showed selective response to imagery of faces (O'Craven and Kanwisher., 2000; Cox, D., *et al.*, 2004) and during periods when subjects perceive a face rather than a non-face when binocular rivalry is created by presenting different stimuli to each eye (Tong, F. *et al.*, 1998).

2.21.3.5.2 The nature of the face representation in face-selective regions

Several studies suggest that the FFA contributes to face identification. Grill-Spector K. *et al.* (2004) reported that the FFA response is modulated by successful recognition of familiar faces. Yovel G. and Kanwisher N. (2005) employed an event-related fMR-adaptation design in which the response to different stimuli is compared to the response of identical stimuli. A higher response to different than same pairs suggests that a given region is sensitive to the difference between the stimuli (for review see Grill-Spector, K. *et al.*, 2006). Findings show fMR-adaptation effect for unfamiliar upright faces in the FFA, but importantly non-face-selective regions, such as the object general lateral occipital complex (LOC), showed no fMR-adaptation for faces (see Figure 7).

As reviewed in Section 1, cognitive studies have demonstrated that faces are processed holistically. Do face-selective regions generate this holistic representation? Several early studies compared the response to upright and inverted faces in FFA and found a similar response to both. More recent studies however that measured fMR adaptation revealed that the

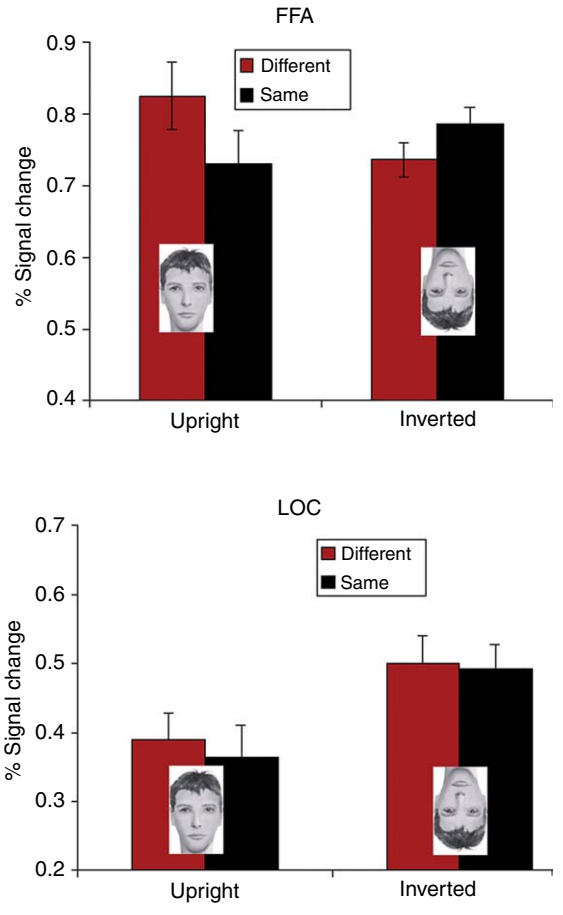

Figure 7 fMRI adaptation to same and different pairs of faces in the fusiform face area (FFA) and lateral occipital complex (LOC). FFA shows greater activation in response to different upright face pairs than same pairs. This adaptation is specific to upright faces in FFA in that LOC does not show adaptation to upright faces and neither FFA nor LOC show adaptation to inverted faces.

FFA showed a larger adaptation effect to upright than inverted faces (Yovel, G. and Kanwisher, N., 2005; Mazzard *et al.*, 2006; Schiltz, C. and Rossion, B., 2006), which is consistent with the behavioral phenomenon of better discrimination of upright than inverted faces. Interestingly, the general object region (LOC) showed an opposite effect of larger response to inverted than upright faces and no fMR adaptation to identity of upright or inverted faces (see Figure 7). These findings highlight the specialized representation for faces in face-selective mechanisms.

However, as mentioned above, the magnitude of the face inversion effect is not a direct measure of holistic processing. To directly assess the extent to which faces are represented holistically, paradigms such as the composite face task (Young, A. W. *et al.*, 1987) have been employed during fMRI experiments. Schiltz C. and Rossion B. (2006) found larger adaptation effect for aligned than misaligned faces, which is consistent with the behavioral composite effect in which identical half-faces are perceived as different faces when they are aligned to different faces than when they are misaligned.

2.21.3.5.3 Two other face-selective regions: occipital face area and superior temporal sulcus

In addition to the FFA, two other face-selective regions are commonly found in most fMRI studies: a region in the posterior STS and a lateral occipital region known as the occipital face area (OFA; see Figure 5). Several studies have shown clear dissociations between the role of the STS and FFA in face processing. The first study reporting such a dissociation revealed greater FFA activation when subjects attend to identity information than to gaze information and the opposite effect in the STS (Hoffman, E. A. and Haxby, J. V., 2000). These and other studies have led to the suggestion that the STS extracts dynamic aspects of face information such as emotion or gaze direction whereas the FFA represents nondynamic face information such as identity and sex (Haxby, J. V. *et al.*, 2000). Consistent with this finding, Grill-Spector K. *et al.* (2004) did not find modulation by successful face recognition in the STS, and Yovel G. and Kanwisher N. (2005) revealed similar response to same and different pairs of faces in the STS (no fMR adaptation). Furthermore, although both the FFA and the STS show lower response to inverted than upright faces, only the FFA inversion effect is correlated across subjects with the behavioral inversion effect as measured in a face identity discrimination task (Yovel, G. and Kanwisher, N., 2005).

The role of the OFA in face processing is less clear. For example, Rotshtein P., *et al.* (2005) presented subjects with pairs of different morphed famous faces that were either perceived as the same identity or were perceived as different identities. The FFA showed fMR adaptation for different morphs that were perceived as the same identity but not to different morphed faces that were perceived as different identities, which is consistent with its sensitivity to identity information. In contrast, the OFA appeared to be sensitive to physical differences, because it showed no adaptation to different morphed stimuli regardless of whether they

were perceived as the same identity or different identities. Yovel G. and Kanwisher N. (2005) also found dissociation between the OFA and FFA in a study that examined the role of face-selective regions in the behavioral face inversion effect. Whereas the FFA showed a higher response to upright than inverted faces and a correlation with the behavioral face inversion effect, the OFA showed a similar response to upright and inverted faces and no correlation with the behavioral inversion effect. These findings suggest that the OFA is primarily sensitive to physical information in the face image rather than its specific identity. In summary, the three face-selective regions seem to play different roles in the processing of the complex, rich information in the facial image.

2.21.3.6 Combined Functional Magnetic Resonance Imaging and Electrophysiological Studies of Faces

How face selective are regions showing a face-selective response in fMRI? This question has been impressively investigated by a recent study that combined fMRI and single-cell recording in monkeys (Tsao, D. Y. and Freiwald, W. A. 2006). Three face-selective patches are present in monkeys, and recordings from single cells were carried out in the middle face patch while the monkeys viewed face and various non-face stimuli. Of the nearly 200 visually responsive cells sampled, 97% showed a much higher response to faces than objects and the response to most objects was not significantly different from baseline. Of the non-face objects to which the cells responded, most had shapes similar to faces. These findings suggest that the face-selective response in face-selective areas human reflect the response of areas committed to face processing. The properties of the cells in the middle face patch were similar to the properties of face cells that were reported 20–30 years earlier without the guidance of fMRI (see Section 2.21.3.1 above). These unguided recordings usually found that about 20% of visually responsive cells were face selective, which suggested a seemingly sparse face-selective response. The new results demonstrate that face-selective cells are densely packed and reveal the great promise of studies combining fMRI with single-cell recording.

The relationship between the fMRI and electrophysiological responses to faces has also been assessed in humans in the few studies that collected data with both electroencephalography (EEG) and fMRI in different sessions under similar experimental procedures. Henson R. N. *et al.* (2002) examined the effect of familiarity and repetition with ERP and fMRI. The ERP and fMRI studies were conducted in different sessions on different groups of subjects. By examining the modulation of the N170 and fMRI measures to repetition and familiarity, the Henson R. N. and colleagues attempted to assess whether the N170 originates in the fusiform or the STS face regions. Because the N170 and the STS showed similar right hemisphere laterality and no effect of face familiarity and face repetition, the authors concluded that the N170 is associated with the face activity in the posterior STS. However, Horovitz S. G. *et al.* (2004) examined the effect of different levels of noise in a face on the pattern of response of the N170 and fMRI response to faces. Their results show a similar pattern of modulation of the stimulus on the N170 and the FFA. Recently, Iidaka T. *et al.* (2006) recorded ERP and fMRI using the same paradigm in separate sessions but revealed very weak correlations between the ERP and the fMRI response to faces. So far there have been no studies that recorded ERP and fMRI simultaneously. Hopefully such future studies will shed light on the relationship between temporal (ERP) and spatial (fMRI) aspects of the neural and response to faces.

2.21.4 Neuropsychological Deficits of Face Recognition

Deficits involving face recognition are some of the most dramatic conditions in neuropsychology and have provided powerful evidence that face recognition involves face-specific mechanisms. A variety of face recognition deficits have been documented, but we will focus our review on prosopagnosia, the most thoroughly researched and commonly reported deficit of face recognition.

Prosopagnosia is characterized by severe face recognition deficits which are not due to problems with lower-level visual problems or higher-level semantic problems. Prosopagnosics are usually able to perceive that they are viewing a face and the features that make them up, but they have great difficulties identifying individual faces (Blanc-Garin, J., 1984; Humphreys, G. W. and Riddoch, M. J., 1987; Ellis, H. D. and Florence, M., 1990). The

description of one of Bodamer's patients nicely illustrates the experience of many prosopagnosics:

> S is told to look at his own face in a mirror. At first he mistakes it for a picture but corrects himself. He stared for a long time as if a totally strange object is before him, then reports that he sees a face and describes its individual features. He knows it is his own face but does not recognize it as his own. It could be that of another person, even a woman. (Ellis, H. D. and Florence, M., 1990, p. 86).

This patient not only had deficits with facial identity recognition, but was also unable to discriminate gender from the face and other observations demonstrated that he was unable to recognize facial expressions of emotion (Ellis, H. D. and Florence, M., 1990). General deficits with face processing including expression, gender and identity are not uncommon in prosopagnosia (Bornstein, B., 1963; Ellis, H. D. and Florence, M., 1990; Duchaine, B. *et al.*, 2006), but dissociations between the processing of facial identity and other face-processing abilities have been reported (Duchaine, B. *et al.*, 2003) and suggest that different types of face processing involve separable components (Bruce, V. and Young, A. W., 1986; Haxby, J. V. *et al.*, 2000; Duchaine, B. *et al.*, 2006; but see Calder, A. J. and Young, A. W., 2005).

Prosopagnosia often leads to serious social difficulties. Prosopagnosics' failure to recognize acquaintances, friends, or family members can be perceived as an intentional snub and create offense when none is intended. Prosopagnosics who have contacted our laboratory have sadly described lost romantic opportunities, workplace disasters, and strained family relations due to failures of face recognition. Person recognition in neurologically typical individuals relies on a range of information including voice, gait, hair, body shape, and context, and prosopagnosics rely on these cues to identity (Bornstein, B., 1963; Duchaine, B. and Nakayama, K., 2006). They also often make use of distinctive facial features such as especially prominent features, moles, or scars (Ellis, H. D. and Florence, M., 1990; Duchaine, B., 2000). However, none of these means is as reliable or efficient as normal recognition of the face. Prosopagnosics not only fail to recognize people, but many also sometimes falsely recognize strangers as familiar (Duchaine, B. and Nakayama, K., 2006).

Until recently, the great majority of studies of prosopagnosia were restricted to patients who lost their face recognition ability due to brain damage. These acquired prosopagnosics were usually well aware of their face deficits, because they recalled how effortless face recognition was prior to their brain damage. In recent years, however, it has become clear that many individuals who have not experienced brain damage have severe deficit with face recognition (Kress, T. and Daum, I., 2003a; Behrmann, M. and Avidan, G., 2005; Duchaine, B. and Nakayama, K., 2006). These individuals are referred to as developmental or congenital prosopagnosics, and this condition appears to be much more common than acquired prosopagnosia.

2.21.4.1 Acquired Prosopagnosia

Given the difficulties that face recognition impairments present to patients, it is not surprising that prosopagnosia following brain damage was documented early on. In the first report in the neurological literature, Wigan A. L. (1844) described a man who could not recognize faces yet reported no other visual problems and could recognize people from their voices. There were a number of other reports of prosopagnosia in the late nineteenth century and early twentieth century (Charcot, J. M., 1883; Jackson, J. H., 1876; Quaglino, A. *et al.*, 2003; see Grusser, O. J. and Landis, T. 1991 for a review), but Hoff H. and Pöltz O. (1937) were the first to suggest that deficits with face recognition was a different disorder than object agnosia. Their patient was unable to identity familiar faces, including his own, but recovered his ability to read and retained some object recognition abilities.

A decade later, Bodamer in 1947 (Ellis, H. D. and Florence, M., 1990) described three patients who showed selective deficits of face perception or recognition subsequent to brain damage suffered in World War II. In his seminal paper, he extended the argument of Hoff H. and Pöltz O. (1937) and coined the term prosopagnosia by combining *prosopon*, the Greek word for face, with *agnosia*. One of Bodamer's patients was able to recognize faces normally but he experienced distortions restricted to faces. This metamorphopsia caused him to perceive faces as stretched or squished and features were sometimes displaced. In contrast, his perception of other objects was normal. The other two patients showed a number of characteristics typical of prosopagnosia. Both had suffered occipital lesions. They were impaired not only with face recognition, but had severe face perception deficits. Patient 1 described faces as "strangely flat, white with emphatic dark eyes, as if made from a flat surface, like white, oval plates, all

alike." Both patients also experienced deficits which sometimes co-occur with prosopagnosia such as object agnosia, cerebral achromatopsia, and difficulties with facial expression. Despite their severe difficulties with face recognition, their deficits were not readily apparent because both men compensated well by relying on non-facial information.

Since Bodamer's landmark paper, well over 100 cases of acquired prosopagnosia have been documented in the literature (see Farah, M. J., 1990; Grusser, O. J. and Landis, T., 1991 for reviews). These cases have contributed to debates about the neural areas involved in face recognition (Landis, T. *et al.*, 1986; Barton, J. J. *et al.*, 2002; Bouvier, S. E. and Engel, S. A., 2006), the nature of the mechanisms carrying out face recognition and face processing more generally (Damasio, A. *et al.*, 1982; Bruce, V. and Young, A. W., 1986; Farah, M. J., 1990; Farah, M. J. *et al.*, 1995), and even consciousness (Bauer, R. M., 1984; de Haan, E. *et al.*, 1987). However, despite the considerable research investigating acquired prosopagnosia, our understanding of this fascinating condition remains limited.

2.21.4.1.1 Frequency of acquired prosopagnosia

A number of studies have attempted to estimate the frequency of prosopagnosia in patients who have suffered brain damage. Such estimates are, of course, dependent on the criteria used for classification, the method by which patients are obtained, and the time since the event causing the brain damage. In the earliest studies addressing this issue, Hecaen H. and Angelergues R. (1962) found that only 6% of 382 patients who had suffered unilateral or bilateral posterior lesions experienced prosopagnosia. This low estimate was followed by a report from Gloning I. *et al.* (1967) that only one out of 241 patients with lesions to occipital or nearby areas experienced pure prosopagnosia. Similarly, Zihl J. and von Cramon D. (1986) reported that none of their 258 posterior lesioned patients had isolated prosopagnosia.

As we discuss below, prosopagnosia is often accompanied by a number of other deficits so strict criteria regarding purity are likely to make it appear extremely rare. Valentine T. *et al.* (2006) tested 91 brain-damaged subjects with a battery of cognitive and perceptual tests. These patients were a minimum of 6 months removed from their brain damage. Patients and their caregivers were asked to report on the patient's everyday face recognition abilities. Fifty per cent of patients and caregivers reported that patients would be able to recognize close acquaintances but would have difficulty recognizing people only seen a few times. Test results also indicated that many of the patients had trouble with face recognition, especially unfamiliar face recognition. On Warrington's Recognition Memory for Faces test, 77% scored more than two standard deviations below the mean. On less demanding tests of unfamiliar face memory, 20% were more than two standard deviations below. Many also had difficulties with famous face tests. Although the face recognition impairments many of these patients showed are likely to reflect higher level cognitive problems such as general memory deficits rather than problems with face-specific processes, the high proportion of impaired patients nonetheless indicate that problems with face recognition are more common than past studies suggested.

2.21.4.1.2 Conditions associated with acquired prosopagnosia

Acquired prosopagnosia often results from extensive bilateral lesions and is usually accompanied by a number of other visual impairments. Visual field defects are one of the most common co-occurring impairments. This was discussed by neurologists early on (Faust, C., 1955; Meadows, J. C., 1974), and a recent review found that only 12% of 69 prosopagnosic patients had no field defects (Bouvier, S. E. and Engel, S. A., 2006). Especially likely are defects in the left superior quadrant which result from lesions to the right inferior bank of the calcarine sulcus. This association fits nicely with neuroimaging (Sergent, J. *et al.*, 1992; Bentin, S. *et al.*, 1996; Kanwisher, N. *et al.*, 1997) and behavioral evidence (Levy, J. *et al.*, 1972; Gilbert, C. and Bakan, P., 1973; Christman, S. D. and Hackworth, M. D., 1993) indicating left visual field/right hemisphere dominance for face processing. Among the 41 patients in the review mentioned above who had visual field defects that could be assigned to a quadrant(s) or central vision (Bouvier, S. E. and Engel, S. A., 2006), 34 had defects in the upper left quadrant and 13 of these patients had defects restricted to this quadrant. In contrast, 22 had defects in the upper right field but only one patient had defects limited to it. Similarly, 15 had lower left defects and no patients had defects restricted to it.

Difficulties with face processing tasks other than identity computations are also common in acquired prosopagnosics. The quote about Bodamer's patient 1 revealed his problems with nonidentity face computations and similar difficulties have been repeatedly noted (Bornstein, B., 1963; Bowers, D. *et al.*, 1985;

Davidoff, J. B. and Landis, T., 1990; Ellis, H. D. and Florence, M., 1990; Humphreys, G. W., *et al.*, 1993; McNeil, J. and Warrington, E., 1993; de Renzi, E. and di Pellegrino, G., 1998; Humphreys, K. *et al.*, 2007). Some individuals with face recognition impairments have shown normal emotion recognition (Bruyer, R. *et al.*, 1983; Tranel, D. *et al.*, 1988), but Calder A. J. and Young A. W. (2005) have argued that limitations in these papers raise the question of whether identity and emotion can dissociate when tested under comparable conditions.

Object agnosia is also commonly associated with prosopagnosia. Below in our discussion about the specificity of prosopagnosia, we review cases that indicate that object and face recognition are dissociable, but the long-running debate revolving around this question (Damasio, A. *et al.*, 1982; Farah, M. J., 1990; McNeil, J. and Warrington, E., 1993; Moscovitch, M. *et al.*, 1997; Gauthier, I. *et al.*, 1999; Duchaine, B. and Nakayama, K., 2005) makes it clear that such dissociations are uncommon. Particularly rare are dissociations between recognition of individual objects (this car, this bird) and recognition of individual faces.

Meadows J. C. (1974) reviewed the many cases manifesting prosopagnosia and cerebral achromatopsia, and in their recent review, Bouvier S. E. and Engel S. A. (2006) found that the two conditions commonly co-occur. Of 73 cases of prosopagnosia they reviewed, 38 (52%) were also achromatopsic, and out of 38 achromatopics, 17 were prosopagnosic (Bouvier, S. E. and Engel, S. A., 2006).

Deficits impairing navigational abilities (topographagnosia) are also regularly seen. In some cases, representation of large-scale spatial information is impaired (Bornstein, B., 1963) while others are unable to recognize places (Bornstein, B., 1963). In the early analysis of Hecaen H. and Angelergues R. (1962) of the co-occurrence of prosopagnosia and topographagnosia in a large group of patients with unilateral lesions, they found that 38% of prosopagnosics also suffered from topographagnosia and that 77% of patients with topographagnosia were prosopagnosic. Landis T. *et al.* (1986a) examined their co-occurrence in 16 patients with topographic deficits and confirmed prosopagnosia in seven of these individuals.

2.21.4.1.3 Lesion location in acquired prosopagnosia

Neuroimaging and neurophysiology have demonstrated that occipitotemporal areas show a selective response to faces, particularly areas in the right hemisphere (Gross, C. G. *et al.*, 1972; Kanwisher, N. *et al.*, 1997; McCarthy, G. *et al.*, 1997). The consistent association of left field defects with prosopagnosia also argues for a right occipitotemporal locus for face recognition processing (Bouvier, S. E. and Engel, S. A., 2006), and studies of individuals born with cataracts demonstrate that the development of face recognition is more dependent on the right than the left hemisphere (Le Grand, R. *et al.*, 2003). In line with these findings, lesions in this region are crucial for acquired prosopagnosia. In fact, the debate about which areas were responsible for prosopagnosia centered not on whether right hemisphere lesions were necessary but whether they were sufficient (Hecaen, H. and Angelergues, R., 1962; Meadows, J. C., 1974; Landis, T. *et al.*, 1986b; de Renzi, E. *et al.*, 1994; Barton, J. J. *et al.*, 2002; Mayer, E. and Rossion, B., 2006). Most cases of prosopagnosia occur in individuals with bilateral lesions, so the decisive test cases were the few patients with unilateral lesions. With the advent of neuroimaging, this question has become much easier to address as it was no longer necessary to rely on autopsy findings. In recent years, structural imaging has demonstrated that lesions restricted to the right hemisphere are sufficient to cause prosopagnosia (Landis, T. *et al.*, 1988; Sergent, J. and Villemure, J. G., 1989; Sergent, J. and Signoret, J. L., 1992; Marotta, J. J. *et al.*, 2001; Barton, J. J. *et al.*, 2002; Uttner, L. *et al.*, 2002; Wada, Y. and Yamamoto, T., 2001). A few prosopagnosic cases have also been reported following lesions or atrophy not affecting posterior areas but more anterior temporal areas (Evans, J. J. *et al.*, 1995; Bukach, C. M. *et al.*, 2006).

Recent papers have attempted to more precisely assess lesion locations and their effects. Rossion and his colleagues carried out detailed structural and functional investigation of P.S., a prosopagnosic with especially face-selective deficits (Rossion, B. *et al.*, 2003; Schiltz, C., *et al.*, 2007; Sorger, B. *et al.*, 2007). These analyses showed that P.S. had lesions where the OFA is normally seen, activation in FFA though no adaptation, and an intact lateral occipital complex (an area selectively activated in object processing). A similar approach with other patients hold much promise. In the review of Bouvier S. E. and Engel S. A. (2006), lesion overlap in prosopagnosia was analyzed. Figure 8 shows the results of this, and as expected, high overlap was seen in right occipitotemporal areas with several peaks. Especially interesting to note is the lesion overlap results in comparison to face-selective activations seen in

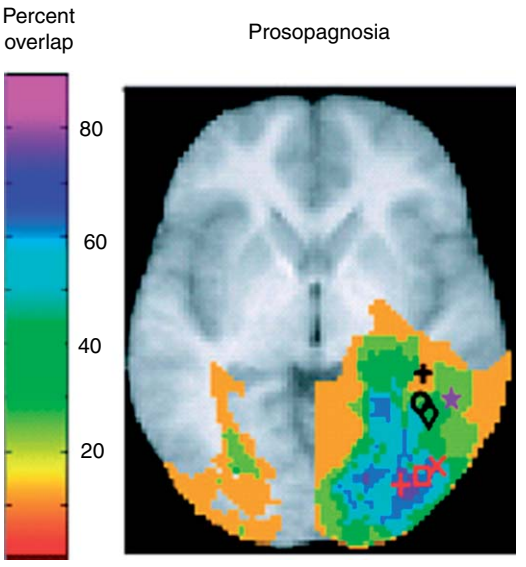

Figure 8 Lesion overlap results compared to face-selective activations in previous experiments with normal subjects. Three areas of peak overlap are shown in blue. Occipital face area activations are shown in red, fusiform face area in black, and superior temporal sulcus in purple. Bouvier, S. and Engel, S., Behavioral Deficits and Cortical Damage Loci in Cerebral Achromatopsia, Cerebral Cortex, 2006, 16, 2, 183–191, by permission of Oxford University Press.

fMRI experiments. The coordinates of OFA fall within the largest area of peak overlap whereas FFA and STS are anterior to this region and lateral to another peak. This suggests that lesions to OFA may be key to prosopagnosia, but given the apparent importance of FFA in face recognition (Grill-Spector, K. *et al*., 2004; Yovel, G. and Kanwisher, N., 2005), it is surprising that FFA did not overlap with a peak. Bouvier S. E. and Engel S. A. (2006) point out that sampling bias may have contributed to this finding as images with medial lesions are more likely to be included in papers because of the availability of landmarks. In discussing this finding, Mayer E. and Rossion B. (2006) also noted that isolated lesions to middle fusiform are rare because it receives blood from both posterior and middle cerebral arteries.

2.21.4.2 Developmental Prosopagnosia

Although Bornstein B. (1963) appears to have noted the existence of developmental prosopagnosia, McConachie H. (1976) provided the first case study of an individual with face recognition deficits in the absence of any identifiable brain damage. A.B. was a highly intelligent 12-year-old girl who reported that she had never been able to recognize faces, except for those with which she was very familiar. She had great difficulty recognizing her uniformed classmates at school. When tested with familiar faces, she hesitantly but correctly identified her friends, and she appeared to score normally on a test of unfamiliar face recognition. She showed normal visual fields, read well, and performed normally on tests of spatial ability and basic level object recognition. Lending support to a developmental etiology, her mother also reported problems with face recognition. Although this case hinted that developmental problems can give rise to prosopagnosia, A.B.'s deficits were not firmly established. In a follow-up study done 15 years later, de Haan E. H. and Campbell R. (1991) clearly demonstrated that A.B. did have face recognition problems as well as facial expression and object recognition problems. Intriguingly, her deficits with tasks other than identity recognition and anecdotal reports that she has navigational problems suggested that developmental prosopagnosia co-occurs with the same conditions as acquired prosopagnosia.

After A.B.'s case was reported, only one new case of developmental prosopagnosia (unaccompanied by autism spectrum disorder) was documented in the 1980s and early 1990s (Temple, C., 1992) so developmental prosopagnosia appeared to be extremely rare. Since that time though, more than 24 papers have reported on developmental prosopagnosics (for reviews, see Galaburda, A. M. and Duchaine, B., 2003; Kress, T. and Daum, I., 2003a; Behrmann, M. and Avidan, G., 2005; Duchaine, B. and Nakayama, K., 2006). The surge of papers is likely the result of the internet allowing researchers and developmental prosopagnosics to make contact and the increased attention to prosopagnosia in the media. Many of these individuals feel great relief upon learning about developmental prosopagnosia, because they finally have an explanation for the great difficulties they have with person recognition.

Like many acquired prosopagnosics (Grusser, O. J. and Landis, T., 1991), developmental prosopagnosics are sometimes able to recognize faces, but they experience severe, recurring problems and many fail to recognize family and close friends (McConachie, H., 1976; Duchaine, B. and Nakayama, K., 2006). Substantial variability in the severity of their face recognition deficit exists among developmental prosopagnosics. Some are able to recognize faces if seen often enough. One man told us that he could

recognize Bill Clinton after a few years of his presidency. Others recognize very few faces. One intelligent Englishman tested in our laboratory watches the news regularly yet failed to recognize Tony Blair, George Bush, Princess Diana, and Prince Charles. They tend to rely on nonfacial information to a much greater extent than people with normal face recognition. Movies and television programs are often difficult to follow because they cannot identify characters. Like acquired cases, many developmental prosopagnosics find ways to maneuver socially by faking recognition until verbal information clarifies identity and by preparing for or avoiding situations in which recognition will be challenging.

Although the prevalence of developmental prosopagnosia has not been firmly determined, it is clear that it is not as rare as once thought. From early 2002 until late 2006, approximately 1900 self-identified prosopagnosics contacted the website of the Harvard/UCL Prosopagnosia Research Center, and more than 1200 of these contacts came in 2006 due to media coverage. Of this sample, the great majority report no history of brain damage and years of difficulty with face recognition. When tested in the laboratory, we find that approximately 80% show severely impaired scores on our tests of face recognition. A German team recently estimated the prevalence of developmental prosopagnosia at 2% of the general population (Kennerknecht, I. *et al.*, 2006). While any estimate of prevalence is strongly dependent on the criteria used for diagnosis, this estimate suggests that there are millions of prosopagnosics in the world. Jane Goodall (Goodall, 1999) reports that she is prosopagnosic, and it appears that Robert Cecil, a late nineteenth century UK Prime Minister, was as well (Cecil, D., 1973). It is interesting to consider that individuals in modern societies are bombarded by faces whereas in ancestral environments the demands of face recognition were much less. In the small bands in which humans evolved (Foley, R. A., 1995), people with face recognition deficits may have been able to navigate the social world much more successfully than they can today.

It appears that a variety of causes can lead to developmental prosopagnosia. The first case study hinted at a genetic cause and other documented developmental prosopagnosics have mentioned that relatives share their difficulties (Duchaine, B., 2000; Behrmann, M. *et al.*, 2005; Duchaine, B. and Nakayama, K., 2005). de Haan E. (1999) found that three members of a family performed poorly on a famous face test. Approximately 30% of the developmental prosopagnosics who contact our website report genetic relatives with face recognition problems, and we have tested a number of families including one with ten affected members (Duchaine, B. *et al.*, 2007). A recent study using self-report data found that the inheritance patterns in seven families were consistent with dominant autosomal transmission (Kennerknecht, I. *et al.*, 2006). We also find that a substantial proportion (approximately 20%) of our contacts report severe early vision problems such as amblyopia, strabismus, and uncorrected myopia. This high proportion is consistent with developmental evidence indicating that visual input in the first months of life is crucial for the development of face processing (Le Grand, R. *et al.*, 2001; 2003). In many cases, there are no hints as to what may have led to prosopagnosia (Duchaine, B., *et al.*, 2003).

2.21.4.2.1 Conditions associated with developmental prosopagnosia

Like acquired prosopagnosia, developmental prosopagnosia shows considerable heterogeneity in the deficits commonly associated with it (Duchaine, B. and Nakayama, K., 2005; Harris, A., *et al.*, 2005; Le Grand, R. *et al.*, 2006). Many of the same deficits co-occur in both conditions, which suggests that developmental prosopagnosia sometimes results from a developmental failure which affects cortical areas near those areas involved with face recognition. Developmental cases sometimes have trouble recognizing facial expressions of emotion (Duchaine, B., 2000; Duchaine, B., *et al.*, 2006), classifying faces by sex (Duchaine, B. *et al.*, 2006), and judging facial attractiveness (Sadr, J. *et al.*, 2004). All documented developmental prosopagnosics perform normally with basic level object naming (car, dog), but many show deficits with tests of recognition of items from within a category (that car, that dog; Behrmann, M. *et al.*, 2005; Duchaine, B. and Nakayama, K., 2005). Also like acquired prosopagnosics, developmental prosopagnosics regularly report severe navigational problems. A.B.'s navigational difficulties were mentioned above, and among the prosopagnosics who have contacted the Prosopagnosia Research Center, approximately 15% report severe problems. In some especially severe cases, the navigations problems have a considerable impact. At present, almost no research has been carried out on developmental navigation deficits.

Although many associated conditions are seen in both forms of prosopagnosia, visual field defects and cerebral achromatopsia have not been reported in any developmental cases. Neuroimaging and neurophysiological work demonstrate that proximity explains their co-occurrence in acquired cases, so the absence in developmental cases is somewhat surprising. However, we expect that visual fields and color vision are often not assessed in developmental prosopagnosia. Lifelong defects such as these may be difficult to self-identify, especially defects limited to a small region of the visual field. Full-fledged achromatopsia would be apparent, but dyschromatopsia would be more difficult to detect.

2.21.4.2.2 Neural bases of developmental prosopagnosia

Given the cognitive heterogeneity in developmental prosopagnosia, it is likely that multiple neural abnormalities will be responsible for it. Studies that have investigated the neural bases in developmental cases have found some atypical neural responses but these atypicalities are not seen in all cases and no correspondence between response variability and cognitive variability has been identified.

Face-selective areas identified by fMRI were a natural first step in neural investigations of developmental prosopagnosia, but so far, few differences between controls and DPs have been found in these areas. Hassan U. *et al.* (2003) found that the magnitude of the FFA in Y.T. was normal, and normal FFA response was also found in a study involving four developmental prosopagnosics (Avidan, G. *et al.*, 2005). In addition, this study examined adaptation in FFA by comparing the response to 12 different faces to that of 12 repetitions of the same face. The developmental prosopagnosics showed adaptation comparable to the controls, which suggests that FFA is sensitive to identity information. However, adaptation in controls and the prosopagnosics was seen in a number of other visual areas, a finding consistent with an attentional account of the weakened response to repetition. Another recent single case study found weaker face activation in left FFA and bilaterally in the temporal poles (von Kriegstein, K. *et al.*, 2006).

The N170 and M170 have also been examined in developmental prosopagnosia. Bentin S. *et al.* (1999) found that the N170 in Y.T. was not as face-selective as controls, and Kress T. and Daum I. (2003b) found similar results in two other participants. In contrast, Harris A. *et al.* (2005) found mixed results when they examined the M170 in five developmental prosopagnosics. Two subjects showed a stronger response to faces than houses that was comparable to that for controls, while three failed to show a face-selective response. Analysis of the behavioral results for the two groups did not reveal any distinctions that mapped on to the M170 differences.

Behrmann M. *et al.* (in press) have reported structural abnormalities in developmental prosopagnosia. Morphometric and volumetric measurements were made in controls and six developmental prosopagnosics. Anterior fusiform gyrus was smaller in the developmental prosopagnosics than in controls, whereas middle temporal gyrus and posterior temporal gyrus were larger in the prosopagnosics than controls. Most impressively, the volume of the anterior fusiform gyrus was positively correlated with performance with famous faces in the developmental prosopagnosics.

2.21.4.3 Face-Specificity in Prosopagnosia

The cognitive and neural sections above described evidence indicating that faces are processed by face-specific mechanisms, and evidence from prosopagnosia has played a key role in the debate about specificity (Farah, M. J., 1990; Kanwisher, N., 2000; Tarr, M. J. and Gauthier, I., 2000). As mentioned above, many prosopagnosics experience both face and object recognition deficits. This association has led some researchers to argue that face recognition deficits are the most obvious manifestation of damage to more general purpose object recognition mechanisms (Damasio, A. *et al.*, 1982; Gauthier, I. *et al.*, 1999). Areas involved in face recognition, however, are adjacent to object recognition areas so an association is to be expected. The theoretically illuminating cases are those which show dissociations between face and object recognition, and such dissociations have been documented in both acquired and developmental prosopagnosia.

To demonstrate a dissociation between face and object recognition, it is crucial to test each at comparable levels of specificity. This has been done by comparing recognition of individual objects from within a category to recognition of individual faces (Davidoff, J., 1986; Moscovitch, M. *et al.*, 1997). A number of acquired cases have shown dissociations under such conditions. W.J. was a sheep farmer who experienced severe face-processing deficits following three vascular episodes (McNeil, J. and Warrington, E., 1993). In contrast, to his profound deficit with

faces, W.J. was able to recognize many of the sheep in his flock of 36 and performed better than all controls (including two sheep experienced controls) on two sheep face recognition memory tests and a paired associates learning test with sheep faces. Similarly, R.M., a car enthusiast who suffered a lesion that left him with profound prosopagnosia, was better able to name the make, model, and year of a large set of cars than any controls (Sergent, J. and Signoret, J. L., 1992). Reports with other acquired cases have found similar results with other non-face categories (Farah, M. J., 1996; Henke, K. *et al.*, 1998; Rossion, B. *et al.*, 2003).

Face-selective deficits have also been demonstrated in developmental prosopagnosia (Nunn, J. A. *et al.*, 2001; Duchaine, B. and Nakayama, K., 2005). The clearest demonstration involved testing the predictions of each proposed account of prosopagnosia in a man named Edward (Duchaine, B. *et al.*, 2004; 2006). His normal performance on a wide range of tests including inverted face matching, within-class object discrimination, non-face configural processing, and expert processing (Greebles and human bodies) showed that his prosopagnosia could not be explained by any of the accounts except the face-specific explanation (Duchaine, B. *et al.*, 2006).

If faces are processed by mechanisms specialized for face processing, cases with object agnosia and normal or relatively spared face recognition should exist. A number of these cases have been documented in brain damaged patients (Bruyer, R. *et al.*, 1983; Assal, G. *et al.*, 1984; Feinberg, T. E. *et al.*, 1986; McMullen, P. A. *et al.*, 2000), and multiple papers have explored the profile of Mr. C.K., an object agnosia with wholly spared face recognition (Moscovitch, M. *et al.*, 1997; Moscovitch, M. and Moscovitch, D. A., 2000). Normal recognition of faces has also been seen in combination with severe place recognition deficits (Carlesimo, G. A. *et al.*, 2001). At present, no developmental cases showing normal face recognition and impaired object recognition have been reported.

Evidence for face specificity has also come from metamorphopsia, a disorder involving perceptual distortions. In his classic paper, Bodamer reported a double dissociation (Ellis, H. D. and Florence, M., 1990): patient 3 reported perceptual distortions restricted to faces whereas patient 1 reported that the edges of all objects in a scene, but not faces, appeared to flicker at times. Davidoff J. B. and Landis T. (1986) reported a woman who perceived all faces to be distorted on the left-side, yet she perceived objects normally. Following a stroke, a prosopagnosic woman experienced several visual preservations including one amazing episode involving a poodle face (Landis, T. *et al.*, 1986b). While sitting on a bus, she observed a poodle sitting on the lap of a person across from her. Upon looking up from the poodle to the people in the bus, she now saw the poodle face instead of a human face on each person (see Figure 9). Her quick exit from the bus did not end this bizarre state, but fortunately after 30 min, the perseveration ended. Her perseveration revealed the specificity of face processing, because the poodle was only pasted on to other faces and not on to any other objects in the visual scene.

2.21.5 Development of Face Recognition

Like the cognitive, neural, and neuropsychological aspects of face recognition, the development of face recognition has received extensive attention. The majority of this work has addressed cognitive development, but neural issues are receiving increasing attention. Developmental studies have revealed much about face processing at different ages but little about the changes that lead to mature face recognition abilities.

2.21.5.1 Face Processing in Newborns

Infants are born with visual systems which, though limited in acuity and color perception, allow them to perceive and respond to coarse aspects of the visual world. Considerable research carried out over the last 30 years has demonstrated that newborns attend to faces more than many other comparable stimuli (Goren, C. *et al.*, 1975; Johnson, M. H. and Morton, J., 1991). This revealing ability was first demonstrated by Goren C. *et al.* (1975) in a study with newborns with a mean age of nine minutes. Each infant was presented with four stimuli which included a schematic face, two scrambled faces, and a blank face. The stimuli traversed 180° arcs in front of the child while the infants' head and eye movements were recorded. The infants looked significantly longer at the schematic face than the other three stimuli. Other experiments have replicated these findings (Johnson, M. H. *et al.*, 1991) and extended them to show that newborns prefer faces with open eyes (Batki, A., *et al.*, 2000) and direct eye gaze (Farroni, T. *et al.*, 2002; see Figure 10).

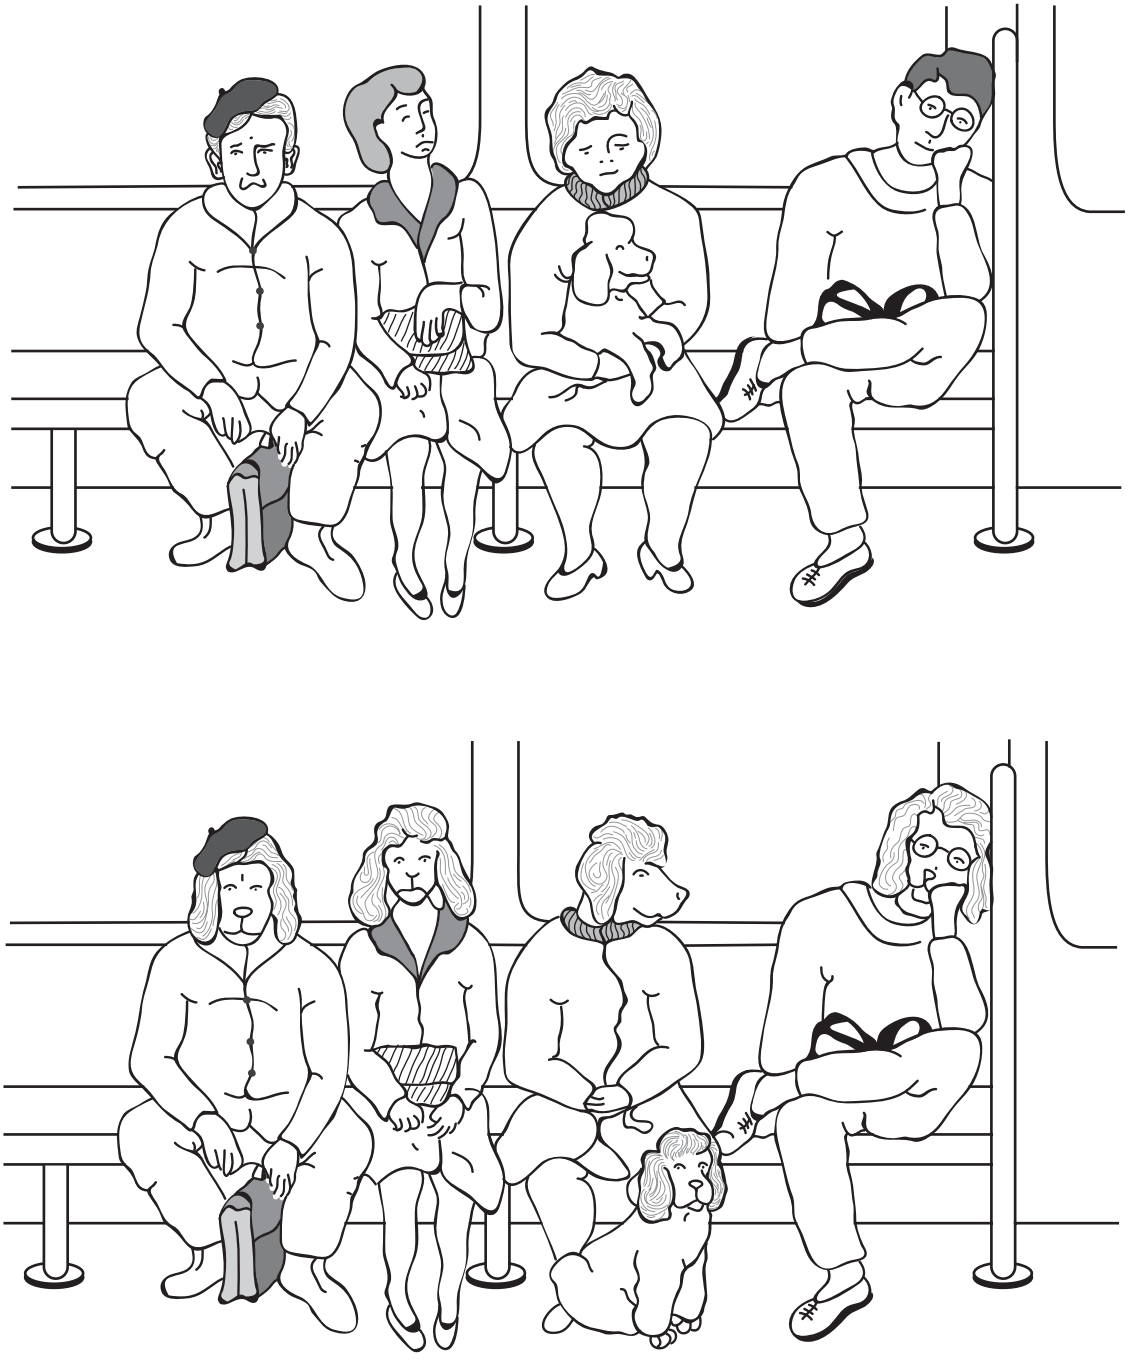

Figure 9 Drawing depicting the visual experiences of a woman experiencing metamorphopsia restricted to faces. Several weeks after suffering a stroke, she rode on a bus and viewed the scene in the top drawing. After looking at the face of the poodle, she looked back to the passengers. However, rather than seeing the faces of the passengers, she saw the poodle's face in place of all the other faces in the bus. This state lasted for approximately 30 min. Drawing by D. Starke.

Newborns also discriminate between different faces. Work examining newborn responsiveness to facial expressions and movements has demonstrated the existence of mechanisms sensitive to the face at birth. Field T. M. *et al.* (1982) found that neonates imitated facial expressions, and Meltzoff A. N. and Moore M. K. (1977) reported that neonates imitated facial gestures such as opening of the mouth and protrusion of the lips or tongue. Newborns also prefer attractive over unattractive faces (Slater, A., *et al.*,

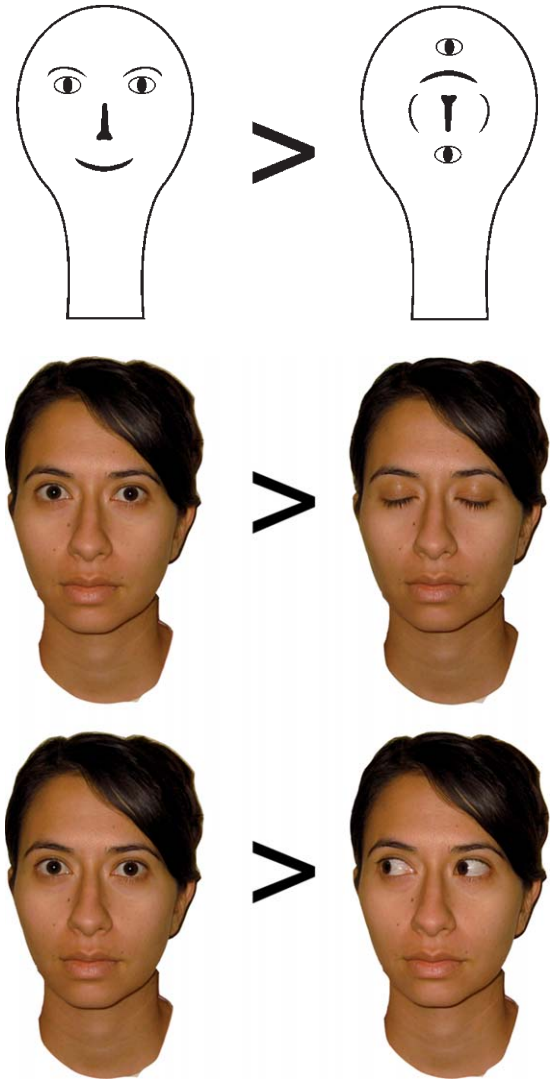

Figure 10 For each pair, newborns attend to the stimuli on the left longer than the stimuli on the right.

1998), and use the internal facial features to make this discrimination (Slater, A. *et al.*, 2000). While these experiments did not investigate face recognition, they clearly show that infants are born equipped to engage with faces.

2.21.5.2 Infant Face Recognition

In first days of life, infants look longer at their mother's face than a stranger's face (Field, T. M. *et al.*, 1984; Bushnell, I. W. *et al.*, 1989; Pascalis, O. *et al.*, 1995). It appears however that these discriminations are based on external features, particularly hair (Maurer, D. and Salapatek, P., 1976; Pascalis, O. *et al.*, 1995). Whether young infants are better able to recognize identity in upright faces than inverted faces is unknown.

The youngest evidence of the inversion effect is seen in infants at 4 or 5 months of age. Using a habituation paradigm, Turati C. *et al.* (2004) found that infants recognized facial identity better when faces were shown in different views in upright faces than inverted faces. Similarly, Bhatt R. S. *et al.* (2005) reported that 5-month-old infants were less sensitive to changes to the spacing of the eyes in inverted faces than upright faces. Neural measures have also demonstrated an early inversion effect. A differential ERP response to upright and inverted was seen in 6-month-old infants (de Haan, E. *et al.*, 2002), and near infrared spectroscopy, which noninvasively records hemodynamic changes, done with 5–8-month-old infants detected a stronger response to upright faces than inverted faces in right lateral areas (Otsuka, Y. *et al.*, 2007).

Recent work suggests that face recognition mechanisms in infants become tuned to the faces observed. Using preferential looking paradigms with infants and discrimination tests with adults, Pascalis O. *et al.* (2002) showed that 6-month-old infants, 9-month-old infants, and adults were able to discriminate between human faces but only 6-month-olds could discriminate between monkey faces. This phenomenon is similar to the loss of sensitivity to phonemes not used in the infant's native language (Werker, J. F. and Tees, R. C., 1984; Kuhl, P. K. *et al.*, 1992). As with phonemes, exposure to monkey faces during the period in which sensitivity is lost extends the period of sensitivity to monkey faces (Pascalis, O. *et al.*, 2005).

Differential processing of faces of different races follows a similar developmental course. Sangrigoli S. and de Schonen S. (2004) and Bar-Haim Y. *et al.* (2006) found that infants at 3 months discriminated between same race faces better than different race faces. This effect disappeared with pretest exposure to other race faces (Sangrigoli, S. and de Schonen, S., 2004). As expected, newborns show no preference for same race faces (Kelly, D. J. *et al.*, 2005).

2.21.5.3 Critical Period in the Early Months of Life

Some of the most revealing developmental studies have investigated face processing in individuals born with congenital cataracts (Le Grand, R. *et al.*, 2001; 2003). The lenses in these individuals were replaced

in the first few months of life, and they had relatively normal visual experience after surgery. Participants ranged in age between 9 and 21 years of age when their face discrimination was tested. Despite years of experience with faces, these individuals showed clear deficits with the face discriminations (Le Grand, R. *et al.*, 2001).

Further research done with participants born with unilateral cataracts, which again were repaired in the first months of life, found eye-specific effects. Cataracts in the right eye had no effect on face discriminations while left eye cataracts led to deficits comparable to those seen in participants with bilateral cataracts (Le Grand, R. *et al.*, 2003). The eye-specific effects are possible, because retinas in infancy are primarily responsive to the temporal visual field (Lewis, T. L. and Maurer, D., 1992) and the immaturity of the corpus callosum appears to make it unable to allow functional integration of visual information (Liegeois, F., *et al.*, 2000). Hence, visual information from each eye is primarily in the contralateral hemisphere. The effect of left eye cataracts indicates that the development of normal face discrimination requires early input to the right hemisphere. Lens replacements were carried out between 2 and 6 months of age, and length of deprivation had no effect on performance (Le Grand, R. *et al.*, 2001; 2003).

2.21.5.4 Face Recognition in Childhood

By 4 years of age, children can be tested using paradigms similar to those used with adults, and results using these paradigms show that children experience many of the same effects considered evidence of face-specific processing in adults. Pellicano E. and Rhodes G. (2003) showed that children as young as 4 years show a part-whole effect, with better recognition of parts within the context of face than in isolation (Tanaka, J. W. and Farah, M. J., 1993). de Heering *et al.* (2006) found additional evidence for holistic processing by demonstrating that 4–6-year-olds showed strong composite effects (Young, A. W. *et al.*, 1987). Similarly, McKone E. and Boyer B. L. (2006) showed that 4-year-olds and adults find that spacing and feature changes have similar effects on distinctiveness judgments.

Although these investigations suggest that face-specific processing procedures operate in early childhood, recognition of unfamiliar faces in children is far from adult levels (Diamond, R. and Carey, S., 1977). What leads to this improvement? Early work suggested that changes in face-processing mechanisms were responsible for much of the change as early studies suggested that the inversion effect was not evident until 10 years of age (Diamond R. and Carey, S., 1977). More sensitive measures however show inversion effects in infancy (Turati, C. *et al.*, 2004; Bhatt, R. S. *et al.*, 2005), and a recent elegant study indicates that the effect of both inversion and contrast reversal are constant from age 8 years through to adulthood (Itier, R. J., and Taylor, M. J., 2004b). Participants had to detect repetitions of upright, inverted, or contrast-reversed faces shown with no lag or a one trial lag. Older participants performed better than younger participants, but the effect of inversion and contrast-reversal had comparable effects on accuracy and response times at all ages. These comparable effects suggest that the improvement seen as children grow older is caused primarily by changes to higher-level processes such as working memory rather than face-specific processes.

2.21.6 Conclusion

Converging evidence from studies that employed cognitive, neural, neuropsychological, and developmental approaches suggest that faces engage specialized processing mechanisms that represent information about faces in a qualitatively different way than inverted faces and non-face objects. In particular, upright faces are represented in a more holistic manner, with the features and the spacing of the features coded more precisely and interactively than other types of objects are. Early studies that employed cognitive methods to examine the nature of the representation of faces in normal and brain damaged patients that suffer from face recognition deficits anticipated the existence of a specific neural substrate for face processing. Indeed, electrophysiological studies and the explosion of neuroimaging work in the last ten years have revealed neural responses that are highly face-specific and seem to play a special role in face recognition processes. A variety of neuropsychological deficits affect face processing. The best studied is prosopagnosia, and it can result from brain damage or a failure to develop face recognition mechanisms. Studies of the development of face recognition revealed that newborns attend to faces more than comparable stimuli and many of the holistic and configural effects emerge early in childhood. Most excitingly, growing connections between

these different levels of explanation are beginning to provide a more integrated theory of face recognition.

Although research into face recognition has led to an outline of what a detailed account of face recognition might look like, many fundamental questions remain unanswered. We still have little understanding of the stages of face processing, what sort of mix of face-specific and more general mechanisms contribute to face recognition, what operations different neural areas carry out, and how the system is modified by experience and maturation. Familial prosopagnosia reveals the existence of genes that are important for the development of face recognition, but little else is known about its genetic basis. Despite scores of neuropsychological studies, no effective treatments for face recognition deficits have been devised. However, the importance of face recognition in our daily life and the existence of specific neural, cognitive and possibly genetic mechanisms that are dedicated to face processing suggest that it will continue to be an area on the cutting edge that provides a model for research investigating other areas in cognitive neuroscience.

Glossary

conjugate eye movements Eye movements of similar amplitude and direction for both eyes.

disjunctive eye movements Eye movements of different amplitude for the two eyes. Disjunctive components are typically quantified by measuring the vergence angle, defined as the difference between right and left eye position.

nystagmus A saw toothlike (zigzag) pattern where slow deviations in eye position are interleaved with oppositely directed quick phases (reflexive saccades) that keep eye position within the oculomotor range.

ocular following reflex Short-latency reflexive eye movements in response to the optic flow experienced during self-motion. These responses, which can be either conjugate or disjunctive, are typically studied during the first ~100 ms of brief presentations of visual motion (open-loop conditions).

optokinetic nystagmus (OKN) A reflexive visuo-ocular response to the en bloc motion of a large visual field that matches slow phase eye velocity to the velocity of the visual surround. Optokinetic after nystagmus (OKAN) refers to the decay of slow velocity to zero after surround rotation stops.

otolith organs Inertial sensors that are located in the inner ear and consist of receptor hair cells with different polarization vectors distributed over the utricular (approximately horizontal) and the saccular (approximately in the sagittal plane) maculae.

retinal image slip Difference between the velocity of the movement of a retinal image and the eye that is picked up by motion detectors in the visual system.

semicircular canal One of the two sets of vestibular end organs that measure angular acceleration of the head. In each ear, there are three semicircular canals: horizontal lateral, anterior, and posterior. Each canal senses angular motion in its respective plane.

vergence The angular difference between right and left eye position. Vergence angle is zero when looking at optical infinity and reaches higher values the closer the target is to the eyes.

vestibular end organs A set of balance receptors in the inner ear, consisting of the otolith organs (utricle and sacculus) that encode linear acceleration and the semicircular canals (horizontal lateral, anterior and posterior) that measure angular acceleration.

vestibulo-ocular reflex cancellation Head movement while fixating a head-fixed target that results in suppression of compensatory eye movements.

2.22.1 Two Types of Vestibulo-Ocular Reflexes

The vestibulo-ocular reflex (VOR) describes a group of eye movements whose goal is to rotate the eyeball in a particular direction and with a specific speed such that the world remains stable on the retina during head movement. The signals driving these eye movements arise from the vestibular labyrinths that house the sensory receptors of our sixth sense, enabling us to detect the movement of our head through space. The vestibular labyrinths contain two types of specialized sensory receptors (Figure 1(a)): (1) three semicircular canals (horizontal, anterior, and posterior) that transduce rotational head movements (angular acceleration); and (2) two otolith organs (utricle and saccule) that sense linear acceleration. Linear accelerations are typically experienced during translational movements and/or reorientations of the head relative to gravity (a form of linear acceleration). Collectively the five vestibular end organs contain sensory neuroepithelia that sense both angular and linear accelerations in three dimensions (3D).

Unlike the five senses described in this encyclopedia, there is limited conscious perception of this vestibular sense, largely because vestibular signals rarely occur in isolation in the central nervous system. Instead, neurons sensitive to vestibular stimulation are typically also responsive to visual, somatosensory, or motor-related signals. The VOR is unique in representing the sole behavior that is driven exclusively by labyrinthine signals. Because of this, as well as its relatively simple neuronal organization, the VOR has often been used to study vestibular function. Depending on whether the head movement consists of a rotation or a translation, these reflexive responses can be categorized into two types, the rotational VOR (RVOR; e.g., when the head rotates to the right, the eyes rotate to the left) and the translational VOR (TVOR; e.g., when the head translates to the right, the eyes rotate to the left). The RVOR represents a phylogenetically old reflex, shared by many invertebrates and all vertebrate species. In contrast, the TVOR is well developed in the primate brain where foveal visual acuity and stereovision are functionally important (Miles, F. A., 1993; 1998; Angelaki, D. E. and Hess, B. J., 2005). This chapter first outlines the unique properties of each VOR type and then describes their neuronal substrates and highly adaptive ability.

2.22.1.1 Rotational Vestibulo-Ocular Reflex: Basic Properties and Frequency Dependence

The RVOR is driven by semicircular canal signals that sense how fast our head rotates. It is studied

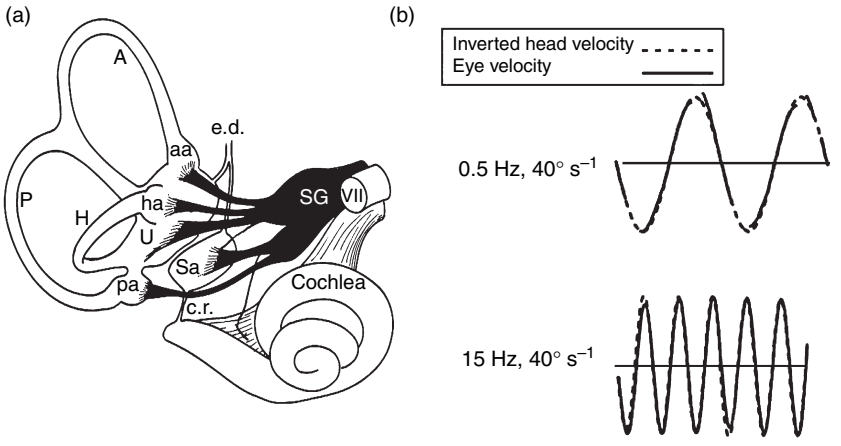

Figure 1 (a) The membranous vestibular labyrinth. Each semicircular canal encodes rotation in a particular plane and has a sensory organ located in an enlargement, the ampulla (aa, ha, and pa, ampullae of the anterior (A), horizontal (H) and posterior (P) canals, respectively). There are two otolith organs that sense linear accelerations, the utricle (U) and the saccule (Sa). The vestibular end organs are innervated by a separate branch of the VIII cranial nerve, whose cell bodies are in Scarpa's ganglion (SG). e.d., endolymphatic duct; c.r., canal reunions connecting the sacculus with the cochlea; VII, facial nerve. Redrawn with permission from Hardy, M. 1934. Observations on the innervation of the macula sacculi in man. Anat. Rec. 59, 403–418. (b) Typical rotational vestibulo-ocular reflex responses during sinusoidal rotation at 0.5 and 15 Hz. Redrawn from Sadeghi, S. G., Minor, L. B., and Cullen, K. E. 2006. Dynamics of the horizontal vestibuloocular reflex after unilateral labyrinthectomy: response to high frequency, high acceleration, and high velocity rotations. Exp. Brain Res. 175, 471–484, Springer.

using either sinusoidal oscillations (Figure 1(b)) or constant velocity rotations (Figure 2(a)). Its goal is to generate an eye movement with a velocity that is matched in amplitude but opposite in direction to head velocity (Figure 1(b)). For large head rotations, the RVOR is often manifested as nystagmus, a saw toothlike (zigzag) pattern where slow deviations in eye position are interleaved with oppositely directed quick phases (reflexive saccades) that keep eye position within the oculomotor range (Figure 2(a), top). The involuntary fast phase segments of the RVOR are generally ignored to facilitate analysis of the more salient slow phase compensatory response segments (Figure 2(a), bottom).

The effectiveness of the RVOR is characterized by its gain, defined as the ratio of eye velocity over head velocity. The exact value of RVOR gain varies from species to species, being largest in monkeys (where horizontal RVOR gain at frequencies above ~0.1 Hz in darkness is close to ideal; that is, ~0.9–1.0; Keller, E. L., 1978), but smaller in humans; that is, ~0.5–0.8; Benson, A. J., 1970; Tweed, D. *et al.*, 1994). High RVOR gains are also typical during rotation at high frequencies (Lasker, D. M. *et al.*, 1999; Huterer, M. and Cullen, K. E., 2002; Ramachandran, R. and Lisberger, S. G., 2005). Like the vestibular periphery that senses movement in 3D, the RVOR represents a 3D reflex (Robinson, D. A., 1982; Tweed, D. *et al.*, 1994; Angelaki, D. E. *et al.*, 1996): yaw (left–right) rotation elicits horizontal eye movements, pitch (up–down) rotation elicits vertical eye movements, and roll (right–left ear down) rotation elicits torsional eye movements.

For sinusoidal rotations, in addition to its gain, RVOR dynamics are also quantified by computing what is called the phase shift, defined as the timing difference between peak head and eye motion. The RVOR phase is typically perfectly compensatory, with phase near 0° (Figure 1(b); Tweed, D. *et al.*, 1994; Angelaki, D. E. and Hess, B. J., 1996; Lasker, D. M. *et al.*, 1999; Sadeghi, S. G. *et al.*, 2006). However, at frequencies lower than ~0.05–0.10 Hz gain declines and progressively larger phase leads are introduced. This occurs because of the properties of semicircular canal afferents, which accurately encode velocity only above ~0.05 Hz (Fernandez, C. and Goldberg, J. M., 1971). As a result, maintained constant velocity rotation results in an initial transient RVOR that decays out over several seconds (Figure 2(a)). Sudden cessation of rotation is encoded by the semicircular canals as a step in the opposite direction, eliciting a response typically referred to as postrotatory nystagmus (Raphan, T. and Cohen, B., 1985; Raphan, T. *et al.*, 1979; Figure 2(a)).

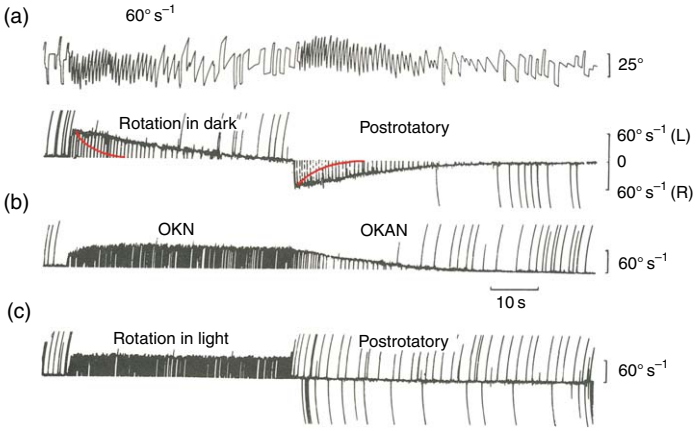

Figure 2 Interactions between the rotational vestibulo-ocular (RVOR) and optokinetic (OKN) reflexes. (a) Nystagmus in response to rotation at constant velocity (60° s^{-1}) in darkness. The top traces illustrate horizontal eye position, whereas the bottom traces plot slow-phase eye velocity (the large positive and negative spikes reflect the occurrence of fast phases). The solid red line in the lower trace illustrates the semicircular canal afferent time course, which is shorter than that of the RVOR. (b) Slow-phase eye velocity in response to a step in surround velocity, generating optokinetic nystagmus and optokinetic after nystagmus. (c) Slow-phase eye velocity in response to platform rotation in light. Note that during rotation in light the postrotatory RVOR and OKAN slow phase velocities are oppositely directed ((a) and (b)). Thus, the two after-responses cancel each other and postrotatory responses during rotation in light are small (c). Reprinted from Raphan, T. and Cohen, B. 1985. Velocity storage and the ocular response to multidimensional vestibular stimuli. Rev. Oculomot. Res. 1, 123–143, with permission from Elsevier.

How fast the RVOR decays is characterized by its time constant, defined as the time over which eye velocity decays to zero. In most species, including primates, the rate at which the RVOR response to a step in head velocity decays is slower than would be expected from semicircular canal afferents (Raphan, T. *et al.*, 1979). The difference represents a central prolongation or perseveration of the raw vestibular signal, referred to as the velocity storage integrator (for review, see Raphan, T. and Cohen, B., 1985). Although such low frequency or long duration stimuli are unnatural, particularly when delivered in darkness, they have been very useful experimentally to study multisensory interactions (for review, see Hess, B. J. and Angelaki, D. E., 1997).

An example of such velocity storage-mediated visual/vestibular interactions relates to optokinetic nystagmus (OKN), a reflexive visuo-ocular response elicited by a large patterned cylinder rotating around a stationary subject (Cohen, B. *et al.*, 1977; Collewijn, H., 1985). Following cessation of drum rotation, eye velocity declines to zero gradually (optokinetic after-nystagmus (OKAN); Cohen, B. *et al.*, 1977; Figure 2(b)). OKN provides a low-frequency complement to the RVOR during rotation in the light. Remember that during constant velocity rotation in darkness eye velocity decays to zero (Figure 2(a)). However, the same rotation in the presence of a visual surround elicits a steady-state nystagmus pattern that is sustained indefinitely, thus stabilizing the world on the retina (Figure 2(c)). This happens because the OKN increases at approximately the same rate as the RVOR decays. Similarly, when head rotation is suddenly halted, OKAN cancels out the postrotatory vestibular nystagmus, such that eye velocity drops quickly to zero. These visual/vestibular interactions are impaired after lesions that also impair velocity storage (Waespe, W. *et al.*, 1985; Schiff, D. *et al.*, 1990).

Activation of the otolith system during rotations that change head orientation relative to gravity also improves the low-frequency RVOR properties (Guedry, F. E., 1965; Baarsma, E. A. and Collewijn, H., 1975; Raphan, T. *et al.*, 1981; Cohen, B. *et al.*, 1983; Hess, B. J. and Dieringer, N., 1990; Angelaki, D. E. *et al.*, 1996). Similar to OKN, these otolith effects on the low-frequency RVOR are also mediated through the velocity storage mechanism (Cohen, B. *et al.*, 1983; Angelaki, D. E. and Hess, B. J., 1994; 1995; 1996).

2.22.1.2 Rotational Vestibulo-Ocular Reflex: Three-Neuron-Arc and Neural Integrator

One of the most important features of the RVOR is its very short latency (<10 ms; Minor, L. B. *et al.*, 1999; Huterer, M. and Cullen, K. E., 2002), which comes about because of a fast sensory vestibular transduction process and a direct, three-neuron-arc pathway (Lorente de No, R., 1935; Szentagothai, J., 1950; Figure 3). The RVOR is organized in a simple push–pull arrangement using signals from both labyrinths. For example, when the head rotates to the right, primary horizontal semicircular canal afferents on the right side increase their firing rates

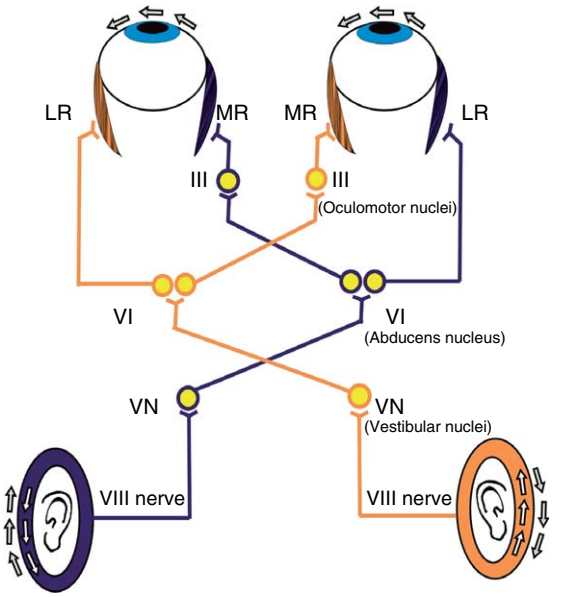

Figure 3 The push–pull organization of the horizontal (yaw) rotational vestibulo-ocular reflex. The direct path consists of a short tri-synaptic reflex consisting of vestibular afferents (VIII nerve), the vestibular nuclei (VN), motoneurons in the VI (abducens) and III (oculomotor) nuclei, and the lateral rectus (LR) and medial rectus (MR) muscles. When the head rotates to the right (arrows), the right horizontal semicircular canal afferents increase their firing rates, whereas the left afferents decrease their activities (orange versus blue colors, respectively). The excitation/inhibition is transmitted to the contralateral/ipsilateral abducens (VI) through neurons in the right/left VN, respectively. Internuclear neurons in the abducens nuclei cross the midline and terminate in the contralateral medial rectus motoneurons (III). Thus, motoneurons in the left VI and right III nuclei fire at a higher frequency, whereas those in the right VI and left III nuclei fire at a lower frequency. As a result, the left LR and right MR muscles contract, whereas the left MR and right LR muscles relax and both eyes rotate leftward.

(Figure 3, orange). This increase in activity is conveyed to the vestibular nuclei in the right side of the brain (Precht, W. and Shimazu, H., 1965) and subsequently through excitatory neuron projections to both motoneurons and internuclear neurons in the left (contralateral) abducens (IV) nucleus (Richter, A. and Precht, W., 1968; Precht, W. *et al.*, 1969). Whereas abducens motoneurons cause the left lateral rectus muscle to contract, internuclear neurons in the left abducens nucleus convey this activity onto medial rectus motoneurons in the right oculomotor nucleus (III; Highstein, S. M. and Baker, R., 1978). Activation of these pathways results in a simultaneous contraction of the lateral rectus muscle of the left eye and the medial rectus of the right eye (Figure 3, orange), causing them both to rotate to the left (open arrows). Importantly, these pathways are bilaterally symmetric, such that during rightward head rotation there is a simultaneous decrease in the firing rates of primary afferents from the left canal, which results in a parallel reduction in the tension of the antagonist muscles (i.e., the left medial rectus and the right lateral rectus; Figure 3, blue). This push–pull organization ensures appropriate yoking of the eyes, generating conjugate eye movements in the opposite direction to head movement.

Although appropriate to account for a fast and conjugate RVOR, the simple three-neuron-arc falls short of explaining other properties of the reflex. In particular, activity in semicircular canal afferents is proportional to rotational velocity, while the reflex generates a compensatory (i.e., of opposite direction) eye position change. Just like in math/calculus, converting velocity to position requires temporal integration. How this takes place in the RVOR has been well documented (Skavenski, A. A. and Robinson, D. A., 1973; Robinson, D. A., 1981). At high frequencies (>0.5 Hz), this transformation occurs automatically by the viscoelastic properties of the ocular plant (eyeball, muscles, and surrounding tissue). However, an additional neuronal circuitry is necessary at low frequencies. Because of this need, Robinson D. A. (1981) proposed a two parallel pathway solution, one of which is the direct three-neuron-arc and the second an indirect pathway that utilizes what has been known as the oculomotor neural integrator (Figure 4). This integrator circuitry involves several cerebellar and brainstem structures, including the prepositus hypoglossi for the horizontal system and the interstitial nucleus of Cajal for the vertical system), as documented by lesion studies (Cheron, G. *et al.*, 1986; Cannon, S. C. and Robinson, D. A., 1987; Fukushima, K., 1991).

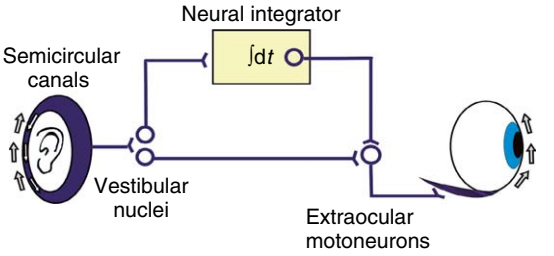

Figure 4 The now classical Robinson-style diagram for the rotational vestibulo-ocular reflex. Semicircular canal signals reach the extraocular motoneurons through two parallel pathways, a direct route through the vestibular nuclei (three-neuron arc; Figure 3) and an indirect pathway that functions like a neural integrator ($\int dt$).

2.22.1.3 Translational Vestibulo-Ocular Reflex: Basic Properties

The TVOR is elicited during translational displacements of the head and body (e.g., when we walk or drive in a car) and is driven by activation of otolith afferents. Unlike the RVOR where a head rotation is compensated by an eye rotation, the TVOR must convert translation into a compensatory eye rotation, a geometrical transformation that makes the magnitude of the evoked eye movement depend on target proximity (Figure 5(a)). Specifically, the same lateral displacement results in nearby objects moving on the retina more rapidly than distant ones. Several studies have indeed shown that the TVOR amplitude scales with vergence angle and the inverse of viewing distance: the eyes rotate by an amount that is larger as the target gets closer to the subject (Schwarz, U. *et al.*, 1989; Paige, G. D. and Tomko, D. L., 1991; Schwarz, U. and Miles, F. A., 1991; Figures 5(b)–5(d)). Like the RVOR, stimuli used to characterize the TVOR include either sinusoidal oscillations (Figure 5(b)) or transient displacements (Figure 5(c)).

A unique feature of the TVOR is that, unlike the RVOR, it often elicits disjunctive eye movements (each eye moves by a different amount). This occurs because the retinal flow experienced during translation can be complex and nonuniform. For example, when moving forward while looking straight ahead, we experience an expanding visual scene (Figure 6(a)) where (1) objects at the periphery of the visual field move faster than those in more central portions of the

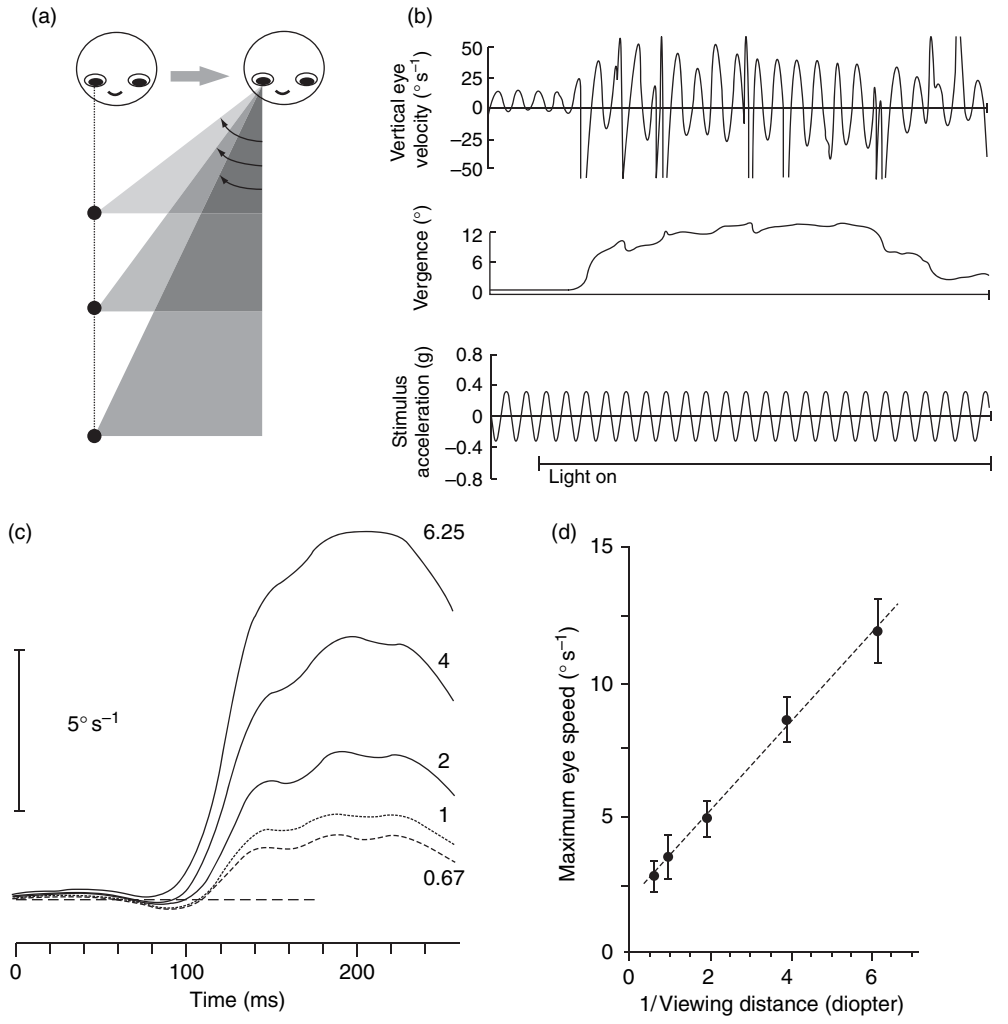

Figure 5 Dependence of the translational vestibulo-ocular reflex (TVOR) on viewing distance. (a) Schematic illustrating the geometry. (b) Eye velocity responses (top) and binocular vergence angle (middle) during 5 Hz oscillations. The monkey was initially in darkness and generated a small amplitude TVOR. After the light was turned on (bar), response amplitude increased as the monkey converged his eyes. Adapted from Paige, G. D. and Tomko, D. L. 1991. retina (similar to the star-field screen saver on a computer); (2) objects appear to move in different directions depending on their spatial location within the visual field; and (3) because forward motion is associated with distance changes, we must converge our eyes to keep images on corresponding locations on the two fovea. As a result, when moving forward while looking to the right, our eyes rotate further to the right (Figure 6(b), blue traces). In contrast, when looking to the left, the same translation elicits leftward eye velocity (Figure 6(b), red traces). The primate/human TVOR is typically undercompensatory for near viewing, with gains of ~0.5 (Paige, G. D. and Tomko, D. L., 1991; Telford, L. *et al*., 1997; Paige, G. D. *et al*., 1998; Angelaki, D. E. *et al*., 2000a; McHenry, M. Q. and Angelaki, D. E., 2000). The residual retinal image motion remaining after a less than ideal TVOR can be nulled by complementary visual stabilization mechanisms, known as the ocular following reflexes (for reviews, see Miles, F. A., 1993; 1998).

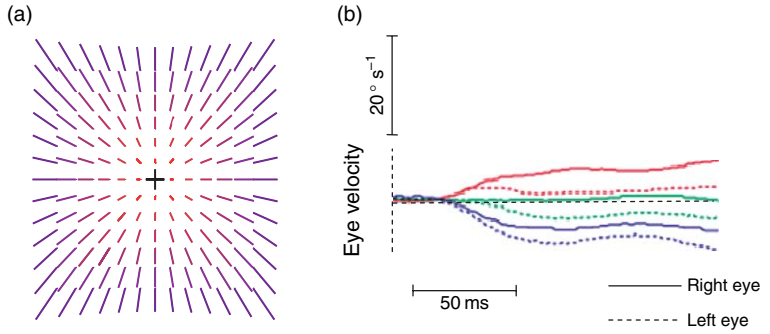

Figure 6 Complexities of the translational vestibulo-ocular reflex (TVOR). (a) Idealized optic flow pattern during forward motion while fixating straight-ahead. Shades from red to blue illustrate transition from the fovea to the retinal periphery. (b) Horizontal eye velocity (TVOR) amplitude during forward motion depends on target position and is disjunctive. Data plot eye velocity of the right and left eyes, while fixating one of three targets ~15° to the left (red), straight ahead (green), or 15° to the right (blue). Upward deflections illustrate leftward eye velocity. Adapted with permission from Macmillan Publishers Ltd: Angelaki, D. E. and Hess, B. J. 2005. Vestibular contributions to gaze stability during transient forward and backward motion. J. Neurophysiol. 90, 1996–2004, with permission from the American Physiological Society.

2.22.1.4 Neural Circuits and Pathways

The main brain areas that participate in the generation of the VORs include the vestibular nuclei (VN) and the vestibulocerebellum, which encompasses the cerebellar flocculus/ventral paraflocculus (FL/VPFL) and the posterior vermis (lobules X and XI). The FL/VPFL is critical for VOR plasticity (see Section 2.22.2.2). The posterior vermis is important for processing signals from the otolith organs and for controlling the RVOR at low frequencies (Solomon, D. and Cohen, B., 1994; Angelaki, D. E. and Hess, B. J., 1995; Angelaki, D. E., 2004). Purkinje cells in the vestibulocerebellum project to the vestibular nuclei, which house both the direct vestibulo-ocular connections (comprising the three-neuron-arc pathway; Figures 3 and 4), as well as some of the indirect projections involved in neural integration (Figure 4). Several VN cell types have been described, differing in their response properties to rotation and smooth pursuit eye movements. In particular, the position-vestibular-pause (PVP) cells are thought to represent the second-order neuron in the three-neuron-arc pathway (Figures 3 and 4; Scudder, C. A. and Fuchs, A. F., 1992). In contrast, eye-head cells, are thought to be involved in VOR adaptation (see Section 2.22.2.2), with many receiving inhibitory projections from FL/VPFL Purkinje cells (Lisberger, S. G. *et al.*, 1994a; 1994b).

2.22.2 Functional Plasticity

The VOR operates in what is called an open-loop fashion, where the signals activating the vestibular labyrinths are independent of the evoked eye movement. Thus, for this reflex to be functionally useful it is critical that the brain continuously monitors its performance by evaluating the clarity of vision during head movement. VOR recalibration is indeed a common experience in everyday life: whenever we try a newly prescribed pair of eyeglasses, we experience discomfort as we adjust to the changed optical magnification. With an increase in magnification, a movement of the head results in a faster movement of the image across the retina and requires an increase in VOR gain to maintain retinal stability. A magnification decrease will require a decrease in VOR gain.

2.22.2.1 Behavioral Observations

The first experimental demonstration of VOR plasticity was by Gonshor A. and Melvill Jones G. (1973; 1976a; 1976b), who studied the effects of wearing reversing prisms in both cats and humans going about their everyday activities. A few days after the prisms were put on, the RVOR (tested in darkness) was greatly reduced, and even reversed direction. Response reversal disappeared almost immediately after prism removal, but the return of gain took

several days. Less dramatic, but possibly more physiologically relevant gain increases and decreases were subsequently obtained with the use of spectacles that magnify or reduce the visual image (Gauthier, G. M. and Robinson, D. A., 1975; Miles, F. A. and Eighmy, B. B., 1980). Other studies used short-term adaptation by exposing the subject to a motion stimulus coupled with an abnormal visual stimulus (Lisberger, S. G. *et al.*, 1983; Raymond, J. L. and Lisberger, S. G., 1996). For example, head rotation paired with rotation of an optokinetic visual stimulus at the same speed but in the opposite direction results in an increase of RVOR gain (Figure 7, top). Similarly, rotating the subject and visual surround in tandem can be used to train the RVOR gain towards zero (Figure 7, bottom). Changes are typically frequency selective, with largest effects at the frequency used during training (Godaux, E. *et al.*, 1983; Lisberger, S. G. *et al.*, 1983; Powell, K. D. *et al.*, 1991; Raymond, J. L. and Lisberger, S. G., 1996). It is also possible to adapt RVOR gain in opposite directions at low versus high frequencies or during the two directions of motion (Hirata, Y. *et al.*, 2002).

RVOR plasticity is not only limited to gain changes. If the subject is rotated horizontally while the visual stimulus moves vertically, horizontal rotation in darkness will generate both horizontal and vertical eye movements (Schultheis, L. W. and Robinson, D. A., 1981; Baker, J. *et al.*, 1986; 1987; Angelaki, D. E. and Hess, B. J., 1998). Adaptive changes in RVOR phase are also possible (Kramer, P. D. *et al.*, 1995). Importantly, RVOR recalibration is context specific: static head position relative to gravity, the position of the eyes in the orbit, and the pattern of head movement have been used as contextual cues for gating different vestibular responses (Baker, J. *et al.*, 1987; Powell, K. D. *et al.*, 1991; Shelhamer, M. *et al.*, 1992; Kramer, P. D. *et al.*, 1998; Yakushin, S. B. *et al.*, 2003). The ability to store multiple calibrations is common in everyday life. For example, once accustomed to new spectacles, no adjustment is needed when the spectacles are removed. Similarly, persons wearing bifocals can instantly shift from one set of optics to the other.

Although less well characterized, the TVOR is also highly adaptable (Seidman, S. H. *et al.*, 1999; Wei, M. and Angelaki, D. E., 2001; Zhou, W. *et al.*, 2003). Notably, the VORs are modifiable not only in response to altered visual/vestibular interactions but also in response to a change in vestibular input brought on by disease or trauma (Paige, G. D., 1983; Fetter, M. and Zee, D. S., 1988; Curthoys, I. S. and Halmagyi, G. M., 1995; Angelaki, D. E. *et al.*, 2000b; Lasker, D. M. *et al.*, 2000; Sadeghi, S. G. *et al.*, 2006).

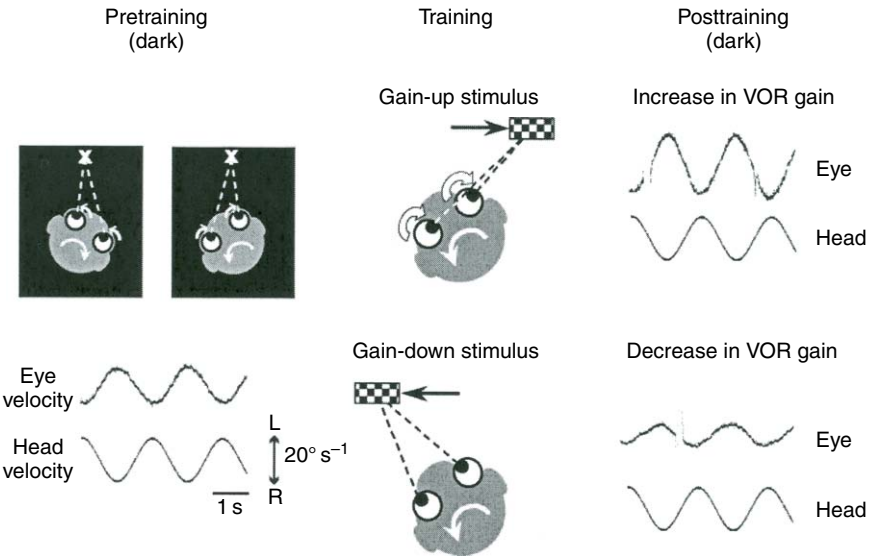

Figure 7 Example of rotational vestibulo-ocular reflex (RVOR) motor learning and adaptation. Prior to adaptation (pretraining dark) the eyes rotate with the same speed but in opposite direction from head rotation. The RVOR gain can be increased (top row) or decreased (bottom row) by simultaneously presenting image motion (OKN stimulus) in either the opposite or the same direction of head rotation, respectively (training). After each training session the RVOR is again measured during rotation in darkness (posttraining dark). Notice the difference in RVOR amplitude. Reprinted from Boyden, E. S., Katoh, A., and Raymond, J. L. 2004. Cerebellum-dependent learning: the role of multiple plasticity mechanisms. Annu. Rev. Neurosci. 27, 581–609, with permission.

2.22.2.2 Neural Signatures of Plasticity: Identifying the Sites for Vestibulo-Ocular Reflex Learning?

Following the theoretical works of Brindley G. S. (1964), Marr D. (1969), and Albus J. (1971) regarding a role for climbing fibers as the teacher signal for synapse modification, Ito M. (1972; 1982) pioneered the cerebellar hypothesis of motor learning, where the FL/VPFL provides a side path to the main brainstem three-neuron arc pathway that is used to adjust reflex performance (Figure 8). Ito proposed that the pairing of visual image motion and head motion causes coincident visually driven and vestibularly driven climbing fiber activity, resulting in long-term depression (LTD) of the corresponding parallel fibers. In this scheme, the instructive signal guiding learning is the retinal slip carried by climbing fibers. Early demonstrations that flocculectomy abolishes RVOR adaptation and LTD at the parallel fiber to Purkinje cell synapse supported this view (Ito, M. *et al.*, 1974; Robinson, D. A., 1976; Ito, M. *et al.*, 1982).

An alternative hypothesis proposed by Miles F. A. and Lisberger S. G. (1981) suggested that the modifiable synapses in the RVOR were located in the VN, while the FL/VPFL Purkinje cells provided the error signal to guide reflex recalibration. The Miles-Lisberger hypothesis was motivated by the observation that changes in Purkinje cell firing during VOR cancellation were often in the wrong direction to support reflex gain changes (Miles, F. A. *et al.*, 1980). However, PVP cells, the main interneurons in the three-neuron-arc pathway, did not exhibit sufficient and appropriate changes after learning (Lisberger, S. G. and Miles, F. A., 1980).

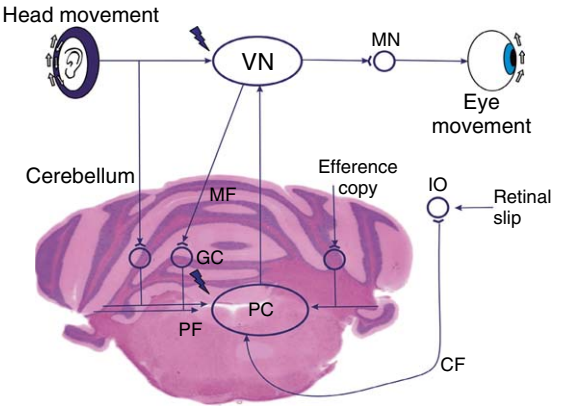

Figure 8 Proposed sites of plasticity for the rotational vestibulo-ocular reflex, one in the brainstem (vestibular nuclei, VN) and the other at the parallel fiber (PF) to Purkinje cell (PC) synapse (arrows). CF, climbing fiber; IO, inferior olive; GC, granule cell; MF, mossy fiber; MN, motoneurons. Adapted from Boyden, E. S., Katoh, A., and Raymond, J. L. 2004. Cerebellum-dependent learning: the role of multiple plasticity mechanisms. Annu. Rev. Neurosci. 27, 581–609.

Lisberger S. G. and colleagues have since described another VN cell type, flocculus-target neurons (FTNs), which receive direct inhibition from the FL/VPFL and monosynaptic inputs from the ipsilateral vestibular nerve (Lisberger, S. G. and Pavelko, T. A., 1988; Broussard, D. M. and Lisberger, S. G., 1992; Lisberger, S. G. *et al.*, 1994a). FTNs exhibited large changes following motor learning that were in the appropriate direction to support the adapted changes (Lisberger, S. G. and Pavelko, T. A., 1988; Lisberger, S. G. *et al.*, 1994b). Importantly, the latency at which these adaptive responses manifested was short, providing further support for FTNs being a site for plasticity (Lisberger, S. G. *et al.*, 1994b; for review, see du Lac, S. *et al.*, 1995). Similar sites for plasticity have also been described for the vertical RVOR (Partsalis, A. M. *et al.*, 1995a; 1995b; Highstein, S. M. *et al.*, 1997.

However, in some circumstances (e.g., during high frequency training), Purkinje cell firing fails to discriminate stimuli that increase and decrease RVOR gain, an observation that is incompatible with the Miles-Lisberger hypothesis (Raymond, J. L. and Lisberger, S. G., 1998). In contrast, several manipulations used to disrupt molecular pathways required for cerebellar LTD produced strong deficits in motor learning (for review, see Boyden, E. S. *et al.*, 2004). Thus, current opinion holds that there are multiple cites of plasticity (Figure 8; lightning bolts). Such a notion has been further supported by *in vitro* studies describing plasticity mechanisms (for review, see Hansel, C. *et al.*, 2001). Part of the argument for having multiple sites of plasticity stems from theoretical considerations showing that parallel changes in the strength of vestibular inputs to FTNs and Purkinje cells are required to maintain system stability (Lisberger, S. G. and Sejnowski, T. J., 1992; Lisberger, S. G., 1994). Notably, distinct differences between increasing and decreasing RVOR gain adaptation (Miles, F. A. and Eighmy, B. B., 1980) might arise because only the former depends on cerebellar LTD. The latter might utilize cerebellar long term potentiation (LTP) (for review, see Boyden, E. S. *et al.*, 2004).

In summary, there remains controversy regarding the sites for motor memory in the RVOR (with a complete lack of similar experiments in the TVOR). Reaching definite conclusions is often difficult and limited by incomplete knowledge of network structure and signal contents, as each can dramatically

influence interpretation of experimental results. Furthermore, sites for neural plasticity have typically been studied only during RVOR gain changes. It is unknown whether the same brainstem/cerebellar sites of plasticity might also apply to other types of VOR learning (e.g., cross-axis adaptation; Quinn, K. J. *et al.*, 1996). Further experimental investigations and the use of innovative analysis techniques that are less sensitive to assumptions regarding network structure are necessary to understand the sites of neural plasticity further. Yet, the richness of behavioral observations associated with different training paradigms points to the existence of multiple potential adaptation sites within the VOR pathways. Multiple plasticity mechanisms might be advantageous for storing motor memories over different timescales, enabling bidirectional amplitude changes, and refining the dynamics of the adapted movement.

Glossary

amniote The largest group of land vertebrates, all originally egg-laying (lepidosaur and archosaur reptiles, birds, mammals).

apomorphy An evolutionarily new feature.

Bilateria Animals with three germ layers (endoderm, mesoderm, and ectoderm) and that show bilateral symmetry. All eumetazoans are Bilateria, except cnidarians and ctenophores.

cladistics The formal science of the study of evolutionary relationships.

deuterostomes Bilaterian animals in which during embryonic development the first opening, the

blastopore, becomes the anus. This includes the chordates as well as echinoderms and hemichordates.
ectopic Outside its normal location.
endothermy The ability to maintain body temperature independently of environmental sources of heat.
Eumetazoa Animals with true tissues – most of the multicellular animals.
homology The concept of sameness in evolution, where a structure can be traced back to a common origin.
homoplasy The concept of independent evolution of structures in different groups.
induction The effect of a tissue on the fate of another tissue, usually mediated by secreted signaling molecules.
innervation The establishment of functional contacts between nerve fibers and other cells.
neural/abneural The side of the auditory papilla where the nerve enters/the opposite side.
paleontology The science of the study of extinct organisms.
phylogeny The study of the evolutionary relationships of organisms.
plesiomorphy An evolutionarily old feature.
protostomes In these bilaterians, the blastopore becomes the mouth. Protostomes can be subdivided into ecdysozoans (molting animals such as arthropods and nematodes) and lophotrochozoans (such as mollusks and annelids). The split of the deuterostomes and protostomes represents one of the first major bifurcations in the phylogeny of eumetazoans.
signaling factor A secreted protein that binds to a cognate receptor to elicit a response. Its effect can be either cell autonomous (in which case signaling is autocrine) or nonautonomous (when signaling is paracrine) or both.
synapse The contact point between a nerve cell and another cell that permits fast signaling.
transcription factor A protein that binds DNA: it will bind to the promoter or enhancer of a particular gene to either activate or repress its transcription. This usually also requires binding of other transcription factors to different promoter or enhancer elements. Their function is cell autonomous.

The first vertebrate hair cells were probably located on the body surface. Such lateral-line organs specialized as a result of selection pressures to better analyze the stimuli from the environment. Hair cells in the inner ear organs of balance of fish also differentiated into different types and this became structurally obvious in the land vertebrates. Following the origin of a middle ear in lepidosaur, archosaur, and mammal ancestors, unique kinds of hair cell specializations arose that are recognizable along and across the respective epithelia. Structural features are accompanied by functional specializations that differ in the various groups, and in birds and mammals, there is a division of labor between two populations of highly specialized hair cells.

3.01.1 Introduction

3.01.1.1 General Considerations

This chapter is concerned with the history and relationships of a special type of sensory cell found in modern land vertebrates that subserves dual functions: detection of sound and of linear and rotational accelerations in the auditory and vestibular parts, respectively, of the inner ear. These sensory cells – the hair cells – are very similar to each other in both structure and function and they also strongly resemble the hair cells in the lateral-line system of fish and Amphibia. While there is little doubt that these sensory cells of vertebrates share the same phylogenetic origin, similar-looking sensory cells are found in quite different groups of organisms such as cnidarians, tunicates, and cephalopod mollusks (octopuses and relatives; reviews in Coffin, A. *et al.*, 2004; Holland, L. Z., 2005). Other sensory cells in organisms such as insects, which also respond to various kinds of mechanical stimuli, do not strongly resemble hair cells but may still have a common evolutionary history. In view of the presence of similar sensory cells in such a wide variety of species, extreme caution is necessary before making any statements concerning the phylogeny of these cells.

This chapter will have two main themes. Following an introduction to some of the important

concepts, it describes first the hair cell types in the various groups of vertebrates and their relatives, with a view to providing an overview of their evolutionary history and of their structural and molecular variation that is linked to sometimes subtle differences in function. Second, it examines some examples of mechanosensory cells from nonchordate animals and seeks to answer the question as to whether these sensory cells have independently evolved to perform similar functions to those of hair cells, that is, whether there is a basis for postulating that they are derived from the same kind of cells in an unbroken descent from a common ancestor (i.e., are they homologous and synplesiomorphic in the cladistic sense?) or whether they are homoplastic or analogous and only resemble each other due to convergence.

The criteria for determining common ancestry for morphological and molecular features are necessarily different and most conclusions must be preliminary in nature. The fossil history of soft-tissue structures such as sensory cells is virtually nonexistent, so any hypotheses based on the molecular constituents of sensory cells will probably never really be testable using comparisons of the morphological features of fossil organisms.

3.01.1.2 The Concepts of Morphological Homology and Molecular Homology

Homology is both a simple and an elusive concept. At its heart is the idea, rooted in comparative anatomy, of similarity due to common descent, and some have called it the central concept for all of biology (Wake, D. B., 1994). Classically, similarity was measured using a number of criteria: the relative position of a structure with respect to other structures, their continuity through intermediate forms, their connectivity to adjacent structures, their similarity in structural detail and histology, and the correspondence of their developmental origins (Remane, A., 1952; Brigandt, I., 2003). Other, more inclusive and tolerant concepts of homology, such as West-Eberhard's M. J. (2003) broad-sense homology, have not yet shown their usefulness in establishing ancestry and thus play no essential role in the discussion below. Homoplasy, that is, a similarity due to convergence, parallel evolution, and recurrence, needs to be identified; failure to recognize the characteristics of the homology concept can lead to fundamental misunderstandings of statements on evolutionary, historical commonality that are made from within different disciplines. These distinctions have become important since, in the last century, biology branched out into different experimental fields that use widely different techniques and seek different kinds of biologically relevant information (Brigandt, I., 2003). With regard to the discussion of mechanosensory cells, the usages of the homology concept in comparative biology show some very important differences.

Using the criteria defined above, comparative anatomists recognize structures in different species that are considered to correspond to each other and the inclusion of paleontological, comparative-anatomical evidence can provide powerful support for this notion. Homology in this context is a qualitative notion and structures or organs are either homologous or not. In molecular biology, however, the concept of homology is used in the context of the structure of genes and of the proteins they encode. The main criterion by which genes are considered to be homologous is the sequence of nucleic acids in the DNA or in their protein amino acid sequences. This concept is a quantitative one, in which it is said that two sequences are homologous to a certain degree (% sequence identity). At this level, the statement of homology permits comparisons between sequences with reference to their probable functions but only gives a statement of probability about the evolutionary origin of the sequences or about a potential common ancestor (Patterson, C., 1988; Brigandt, I., 2003).

Developmental biologists interested in evolutionary questions are faced with the problem of attempting to reconcile these two usages of homology, since at the level of organismic development, the question of the genetic control of ontogeny and the commonality of evolutionary history overlap. It would of course be expected that a homologous structure would be derived during ontogeny by the actions of the same set of genes, expressed in the same order at the same location in the body's bauplan. Since, however, genes can be involved in a wide variety of developmental processes and single genes may change their sequence during evolution and the gene may therefore change its function, the genetic background that leads to the building of homologous structures may in fact change over time. In addition, genes may become duplicated and diverge in their sequences. Orthologous genes are homologs that diverged as a result of a speciation event, whereas paralogous genes are homologs that diverged as a result of a gene duplication event (Hillis, D. M.,

1994). Here, the qualitative homology of comparative anatomy with its emphasis on common ancestry needs to be reconciled with the quantitative homology of molecular biology, a nontrivial problem indeed. For the purposes of the present chapter, concepts of evolutionary sameness need to be considered at different levels, especially those of the mechanosensory cells themselves, and also their integration into sensory organs in different animal groups. It is not sufficient to propose homology on the basis of the expression patterns of a few common genes (Adam, J. *et al.*, 1998).

A further distraction arises from the fact that frequently, homologous organs for hearing – or auditory organs – in terrestrial vertebrates are sought in invertebrate animals. As Budelmann B. U. (1992) pointed out, this is misguided, since all the invertebrate ancestors that come into question were aquatic and possessed sensory structures geared to respond to a variety of stimuli but not to classical auditory stimuli. To quote Budelmann B. U. (1992): "... any attempt to draw a direct evolutionary line of sound receptors or of hearing from any of the invertebrate groups, or via the hemi- and urochordates, to vertebrates must certainly fail. Also, we should not expect to find a direct *homolog* [his italics] precursor of the vertebrate hearing organ, or any other sense organ, in any of the invertebrate groups." Thus the search in the invertebrate phyla for homologs of vertebrate hair cells must be restricted to the search for possibly homologous sensory cells and their underlying genetic developmental background.

3.01.1.3 What Is a Ciliated Mechanoreceptor Cell?

Put briefly, the cells that are dealt with in this chapter are sensory elements that have a modified cilium (that arises from a basal body) that in some way is implicated in the cells' ability to respond to mechanical stresses of the cell membrane. Typically, such cells harbor certain ion-channel complexes in the cell membrane that are anchored both to the cell's cytoskeleton and outside the membrane to some nearby structure (Gillespie, P. G. and Walker, R. G., 2001). The channel can thus be mechanically stressed by changing the distance between the anchor points and this stress changes the open probability of the transduction (channel), increasing the flux of positive ions into the cell and thus depolarizing it.

As will become evident in this chapter, however, there is as yet no certainty that such mechanoreceptor cells of all animal species are derived from a common ancestral type, especially as mechanosensitive ionic channels are known even from bacteria and were thus most likely developed even before eukaryotic cells evolved. There are thus real problems in deciding evolutionary histories, especially when comparing on the one hand the ciliated mechanoreceptor cells of the chordates and their subgroup the vertebrates, which are specialized epithelial cells (hair cells, Figure 1) and thus belong to the group of secondary sensory cells, and on the other hand the ciliated mechanoreceptors of nonchordate groups that are, with few exceptions, specialized neurons with their own axon (Figure 1) and are thus primary sensory cells. In addition, these two kinds of cells show a fundamental difference in the involvement of the cilium in the sensory process. In the evolution of the vertebrate-type hair cell, the involvement of the cilium seems to have been steadily reduced until it may only be important in establishing the polarity of the cell's sensory outer segment (that consists of large microvilli or stereovilli) and, in some systems, is lost entirely during ontogeny. Not only in the primary ciliated mechanoreceptors, by contrast, but also in secondary ciliated mechanoreceptors of cephalopod mollusks, the cilium is an integral part of the sensory response apparatus and in many cases acts without the involvement of stereovilli.

In both kinds of receptor cells, the cilium is generally nonmotile, that is, the normal ability of the cilium to beat has been lost and is obviously not a requirement for the mechanosensory function. Instead, as in visual sensory cells of numerous animal groups (where the cilium has a vastly enlarged outer membrane segment based on a cilium), the cilium has been co-opted for another purpose. The original reason for the involvement of the cilium in chordate hair cells (and their predecessors, whatever they were) is unclear but may go as far back in evolution to ciliated single-celled organisms whose cilia are responsible for the sensitivity to touch. The cilium, the longest extension of the cell membrane, was perhaps used to anchor the mechanoreceptive channels. The cilium in the hair cell lineage (often called a kinocilium) later became supported by stereovilli, stiffened by an actin core, that form a symmetrical collar around the cilium. With the elongation of these stereovilli and their increase in numbers, the transduction channels

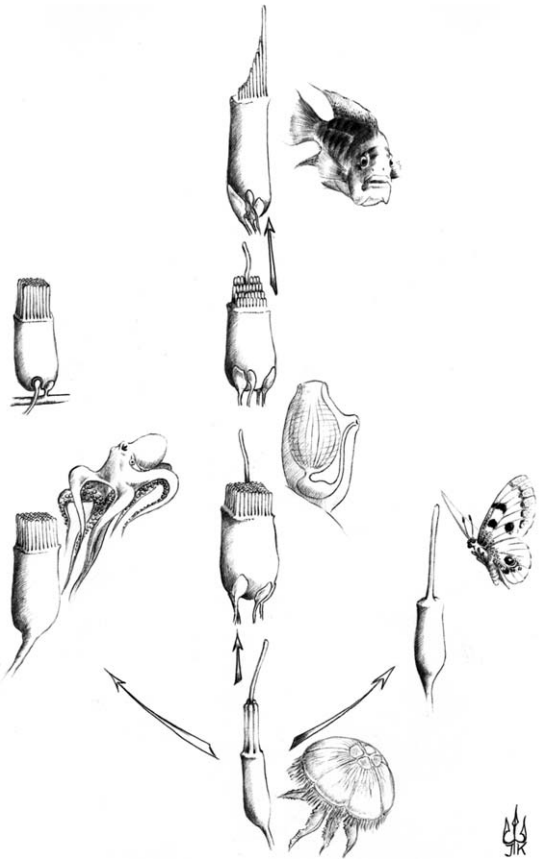

Figure 1 A schematic drawing of the evolution of hair cell like mechanosensitive cells. The figure should be read from bottom to top. Beginning with a mechanoreceptor of a cnidarian that possesses a normal cilium (kinocilium) surrounded by a small number of stereovilli, the evolution of these mechanoreceptors can be traced along three parallel paths in which the stereovilli and kinocilium have different fates. On the left is shown the lineage of the Lophotrochozoa, including annelids and mollusks. In this group, the best-studied case is that of *Octopus*, which possesses both primary (left, lower figure) and secondary (left, upper figure) receptor cells. In both cases, the receptor cells have no stereovilli but large numbers of kinocilia. On the right of the figure, the lineage to the ecdysozoans is shown using the example of insects, where the receptor cells are primary and there are no stereovilli but one enlarged kinocilium. The central lineage leads to the vertebrates (here represented by a fish) via primitive chordate groups, here represented by an ascidian tunicate. In this lineage, all receptor cells are secondary and both kinocilium and stereovilli are preserved. The bundle in vertebrates shows a stepped height of the stereovilli across the axis of sensitivity, with the tallest stereovilli next to the offset kinocilium. In mammals and birds, the kinocilium tends to degenerate during ontogeny. An original drawing by Johanna Kraus, all rights reserved.

apparently at least partly shifted to their membranes. In some lineages, this made the cilium somewhat redundant. In many vertebrate hair cells, one of the main functions of the remaining (kino-)cilium is as a contact area to overlying tectorial structures. In endothermic vertebrates, there is a strong tendency toward reduction or loss of the kinocilium during ontogeny, but the basal body remains in its position and likely plays an important role on the orientation of the bundle of stereovilli during ontogeny. In Ecdysozoa, such as arthropods and nematode worms, the supporting function of stereovilli was taken over by a connection of the cilium to the animal's cuticle. In these animals, therefore, all stereovilli have been lost and now only the modified cilium remains and carries the mechanotransductive channels (Thurm, U., 2001) (Figure 1).

3.01.2 Phylogeny, Homology, and Homoplasy: The Historical Background of the Animal Groups

It will be necessary to refer to a wide variety of animal groups in this chapter, since cilia-bearing mechanoreceptive cells have been described from the group considered to be the most primitive of the Eumetazoa (multicellular animals with true tissues), that is, the Cnidaria or jellyfish. In addition to their stinging cells that use a cilium as the sensor element, these organisms have small sensory organs, statocysts, able to encode to the brain the direction of gravitational force. It is believed that the eumetazoans are monophyletic, that is, have a single common origin. Therefore it may be expected that all following groups have inherited the ability to form such cells. However, abundant evidence from other sensory modalities and from considerations of the complement of cell-membrane channels that multicellular animals have inherited from their single-celled ancestors indicates that, although the genetic basis for mechanosensation exists in multiple cell types, it may only be expressed in a limited and varied subset. The question of homology at the level of cell types is thus not trivial.

The eumetazoans are extremely diverse and we will be concentrating on those groups that have been reasonably well studied. All other groups will not be mentioned or even shown in diagrams. A cladistic (phylogenetic) presentation of the groups to be

discussed is as follows (an indent step to the right indicates a subordinate group):

Common ancestor of eumetazoans
- Cnidaria (jellyfish)
- Common ancestor of bilaterally symmetrical eumetazoans
  - Ecdysozoa
    - Pseudocoelomata (e.g., nematode worms such as *Caenorhabditis*)
    - Arthropoda (e.g., insects such as the fruit fly *Drosophila*)
  - Lophotrochozoa
    - Molluska (e.g., the cephalopod *Octopus*)
  - Deuterostomia
    - Chordata
      - Tunicata (e.g., sea squirts)
      - Acrania (lancelets)
      - Craniata
        - Agnatha (Ostracodermi, hagfish, lampreys)
        - Vertebrata (animals with backbones)
          - Chondrichthyes (cartilaginous fish)
          - Osteichthyes (bony fish)
            - Teleostei (modern ray-finned fish)
            - Tetrapoda (land vertebrates)
              - Amphibia
              - Amniota
                - Lepidosauria (lizards and snakes)
                - Archosauria (birds and crocodilian)
                - Mammalia (mammals)

Evolutionary studies indicate clearly that the three major groups Ecdysozoa, Lophotrochozoa, and Deuterostomia diverged from one another very early and have long histories (more than 600 million years) of independent evolution behind them. In that time, their genomes have evolved completely without reference to each other (if we can exclude horizontal gene transfer via, e.g., common bacterial parasites). It might therefore be expected that their sensory substrates have diverged to a significant extent.

In the first section of this chapter, we will discuss the chordates and attempt to trace the history of their structure and function through the ancestral fish to modern aquatic and terrestrial groups. We will describe types of hair cell from the group of the sea squirts or Tunicata, chordate relatives of vertebrates, which may provide insights into possible ancestral states of the hair cells of vertebrates. Since vertebrate chordates are endowed with hard skeletal elements (cartilage or bone) that generally fossilize well, the fossil history of this group is extremely rich and as a result, the phylogenetic history is very well understood. In addition, the contours of some sensory structures are visible in some fossils. The history of hair cells in this group involves dealing initially with cells of the lateral-line system, then with vestibular, and finally with dedicated auditory sensory organs, whereby the functions of these organs may show considerable overlap.

The second part of the chapter will compare cilia-based mechanosensory cells from other major groups, such as the nematode worms and insects from the group of the Ecdysozoa and the cephalopod mollusks from the group Lophotrochozoa. Here, the question will be discussed as to the extent to which the molecular–genetic information concerning a possible homology to vertebrate hair cells is able to provide clear answers to questions of common ancestry.

3.01.3 Ciliated Mechanosensory Cells of Vertebrates and Their Relatives

A growing body of literature has demonstrated considerable heterogeneity in morphology and physiology of vertebrate hair cells in different taxa and even within different end organs of the same species. Electroreceptive sensory cells of vertebrates (which will not be discussed here) were also derived from hair cells (Jørgensen, J., 1989). Since they are no longer mechanoreceptive, their cilium has been lost and any stereovilli present are no longer stiffened.

Several lines of evidence support the presence of hair cells in the very earliest vertebrates, and in vertebrate ancestors, the early chordates. Such evidence includes the presence of hair cells in all craniates (Coffin, A. *et al.*, 2004) and in other chordates. Secondary sensory cells with one cilium and numerous stereovilli occur in tunicates (e.g., Bone, Q. and Ryan, K. P., 1978). Some of these hair cells in tunicates have symmetrical and some even have bilaterally symmetrical bundles (as in vertebrates), making it very likely that vertebrates inherited their basic hair cell pattern from their invertebrate ancestors (Shimeld, S. M. and Holland, P. W. H., 2000; Burighel, P. *et al.*, 2003). These animals, represented today by the tunicates and lancelets, may also have inherited their hair cells from even simpler ancestors going right back to the earliest eumetazoans, the cnidarians.

3.01.3.1 Mechanoreceptors in Tunicate Sea Squirts and Lancelets

Chordates are comprised of three groups: Tunicata (Urochordata, sea squirts, salps, and appendicularians), Acrania (Cephalochordata, lancelets), and Vertebrata (see, e.g., Hennig, W., 1983). There is no doubt concerning the close relationship of the three groups in the phylum Chordata and thus their relevance to questions concerning the phylogeny of vertebrate hair cells. However, the consistent association of vertebrate hair cells and their innervation with ectodermal placodes and neural crest cells, structures that do not occur in nonvertebrate chordates and for which no homologs have been firmly identified, makes considerations of sensory cell homologies difficult.

3.01.3.1.1 Mechanoreceptors in tunicate sea squirts

To illustrate the variety of mechanosensory cells in sea squirts, we will discuss recent data from ascidian tunicates (Burighel, P. *et al.*, 2003; Manni, L. *et al.*, 2004). These animals are filter feeders that are sessile as adults but have freely swimming larvae. As filter feeders, they use large areas of ciliated cells over the gill-slit supports to draw water through the filtering apparatus. Numerous mechanosensory cells are found, and many are presumably involved in monitoring such water currents.

Most of the superficial sensory cells of tunicates are of the primary receptor cell type, carrying their own axon. However, a recently described coronal organ in the oral siphon of ascidians contains secondary mechanoreceptive cells that bear strong resemblances to vertebrate hair cells (Burighel, P. *et al.*, 2003; Manni, L. *et al.*, 2004). This similarity is of great interest in view of the fact that the atrial chamber in these animals bears some ontogenetic and gene-expression similarities to the otic placodes of vertebrates with which hair cells are associated (Burighel, P. *et al.*, 2003). In the coronal organ of these tunicates, there are about 2000 mechanosensory cells which are secondary sensory cells that make contact to two different kinds of nerve fibers, both afferent and efferent. These hair cells are often arranged in rows of large numbers of cells. In addition, the stereovillar bundles (90–95 stereovilli) of the cells sometimes surround the cilium concentrically, but in other cases, the bundle is highly asymmetrical, with the cilium on one side (Figure 2; Burighel, P. *et al.*, 2003).

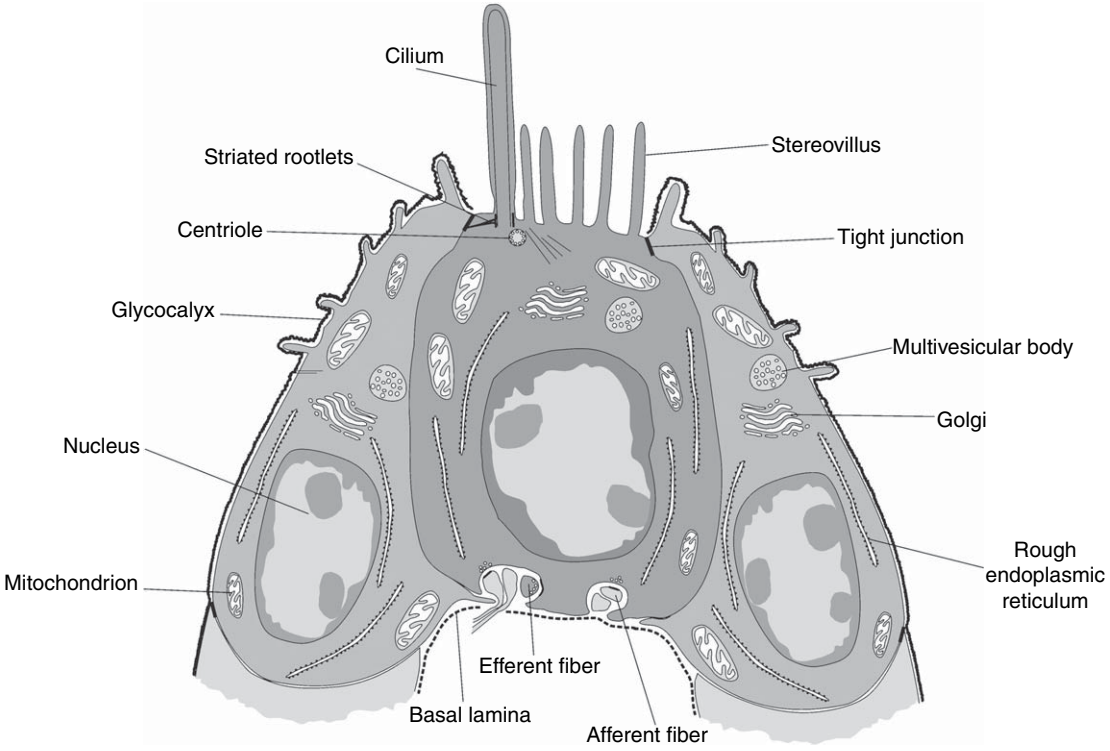

Figure 2 A schematic drawing of a hair cell accompanied by supporting cells in the coronal organ of the ascidian tunicate *Botryllus schlosseri*. Reproduced from Burighel, P., Lane, N. J., Fabio, G., Stefano, T., Zaniolo, G., Carnevali, M. D. C., and Manni, L. 2003. Novel, secondary sensory cell organ in ascidians: in search of the ancestor of the vertebrate latetal line. J. Comp. Neurol. 462, 236–249, with permission from John Wiley and Sons.

The stereovilli of these bundles are either of the same height or graded in height (Manni, L. *et al.*, 2004). In vertebrates, the stereovilli are always arranged such that there is a staircase of height up to the tallest and these are the closest to the cilium or basal body.

The suggestion that the above hair cells are homologous to vertebrate hair cells, even to the vertebrate lateral line (Burighel, P. *et al.*, 2003) has, however, been criticized, since none of the tunicate cells has all the characteristics of a vertebrate hair cell and there is a high degree of variation among ectodermal sensory cells within and between different species (review in Holland, L. Z., 2005). Thus, similarities between the ectodermal sensory cells of any one species of tunicate and craniate hair cells may possibly represent convergent evolution rather than homology. However, Shimeld S. M. and Holland P. W. H. (2000) concluded that since the atrium of ascidians develops from a pair of ectodermal invaginations that are topographically similar to the sensory placodes of vertebrates and since the atrial primordia also express members of the *Pax2/5/8* gene family as in placodes, these factors point to a possible homology between the atrial primordia of ascidia and the otic placodes of vertebrates. This strengthens the view that the hair cells in both the adult structures are also homologous (Manni, L. *et al.*, 2004). Obviously, further studies of the morphology and genetic control of ontogeny of these cells and their surrounding structures are necessary to enable firmer conclusions to be reached.

3.01.3.1.2 Mechanoreceptors in lancelets

The lancelets (often known as amphioxus and placed in a group known as cephalochordates, of which the best known are in the genus *Branchiostoma*) are small marine chordates that are most closely related to the vertebrates. Many primary, but also secondary sensory cells with cilia have been described in this group (review in Lacalli, T. C., 2004). Some are scattered in the rostral epithelium of the juvenile and classified as probable chemoreceptors. Others are in the spines of the mouth of the larvae. These cells bear a cilium, are grouped in clusters, and seem to be mechanoreceptors in synaptic contact with peripheral neurons. However, they do not possess a bundle of stereovilli. Lacalli T. C. (2004) concludes "There are a number of such [secondary receptor] cells in amphioxus, but none is an obvious precursor of any of the secondary sense cells of vertebrates, e.g., [hair cells of] neuromasts, taste buds, or solitary chemoreceptors". Thus with respect to sensory cells that are possible homologs of vertebrate hair cells, the lancelets show less promise than the sea squirts.

3.01.3.2 Vertebrate Hair Cells

3.01.3.2.1 The typical vertebrate hair cell

The hair cells of vertebrates have a typical structure that makes them immediately recognizable (Figure 3). This very strongly suggests that this kind of cell is plesiomorphic to vertebrates and that

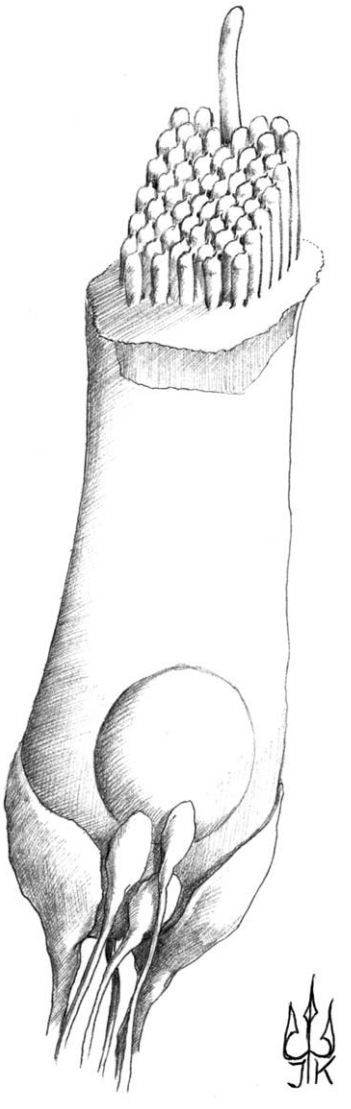

Figure 3 A schematic drawing of a typical vertebrate hair cell. This secondary receptor cell is innervated by both efferent (here drawn as larger synapses) and afferent nerve fibers. The cell bundle is polarized by the staircase structure of the rows of stereovilli that are joined by tip links. The bundle is also bilaterally symmetrical, based on the eccentric position of the kinocilium. An original drawing by Johanna Kraus, all rights reserved.

the first hair cells in vertebrate evolution would have resembled many modern ones. At their apical pole, each hair cell has a sensory hair bundle that is the sensory outer segment responsible for mechanoelectrical transduction (for reviews see Hudspeth, A. J., 1985; 1989). The bundle consists of a true cilium (in this context often referred to as a kinocilium and only lost during development in mammal and bird hearing organs and in electroreceptors) and a (generally shorter) bundle of large, stiff microvilli known as stereovilli (or, confusingly, stereocilia). The cilium is placed eccentrically on the cell surface, and the stereovilli show a gradient in their height, with the tallest next to the cilium. This gradient in height means that the bundle is bilaterally symmetrical and thus polarized in a particular direction.

Although we do not intend to review the detailed structure of such hair cells, we need to mention those features shown to have been the subject of natural selection during vertebrate evolution and thus differ between the hair cells seen in different groups, in different sensory organs, or even within one organ (reviewed in Lewis, E. R. *et al.*, 1985). The stereovillar component of the bundle consists of a number, between about 30 and 300, of rigid stereovilli that may have different thicknesses. The stereovilli are anchored not only in the cuticular plate (an actin matrix) of the hair cell's apex, but also to each other via various connections at different heights up the bundle. The connections between the stereovilli along their shafts help maintain their integrity, whereas the uppermost connections that form between the tip of the next lower stereovillus and the shaft of the taller neighbor (so-called tip links, Pickles, J. O. *et al.*, 1984) play a crucial role in sensory transduction (Hudspeth, A. J., 1989). A very small (a few nanometers) shift of the stereovilli toward the kinocilium puts tension on the mechanotransduction channels and increases their opening probability. This permits positive ions to flow into the cell, depolarizing it, and leading to an increased release of transmitter at the afferent synapse (Hudspeth, A. J., 1989).

The cell body of a hair cell can vary considerably in shape and size, from cylindrical cells with a height of over 70 µm, down to cup-shaped cells with a height of less than 4 µm. To a certain degree, the height of the cell body correlates – at least within the same auditory organ – with the bundle height, short bundles being found on shorter hair cells. The bundle height plays a role in determining the cell's frequency response (shorter bundles correlate with higher frequencies), and such higher frequencies are apparently better processed by smaller cell membranes. Under tectorial cupulae, bundle heights can exceed 130 µm (Lewis, E. R. *et al.*, 1985). The archaic state of vertebrate hair cells sees them connected synaptically to both afferent and efferent nerve fibers and this condition is maintained in almost all hair cell epithelia. The main exceptions are found in the cochleae of mammals and birds, where a clear specialization of the innervation is found, with a strong reduction or loss of the afferent innervation but increase in dominance of the efferent innervation of abneurally lying hair cells (Spoendlin, H., 1978; Fischer, F. P., 1994). In some areas of amniote auditory organs, efferent innervation is also completely lost (Manley, G. A., 2004; Vater, M. *et al.*, 2004).

Many features – visible and submicroscopic – of hair cells can change their stimulus–response properties. The response (depending on the sensory organ) will depend on whether the stereovillar bundle is connected to a gelatinous tectorial structure or not and whether this tectorium contains calcareous otoliths or not. It will also depend on the size, number, and thickness of the stereovilli, which together determine the bundle stiffness; stiffer bundles respond to higher stimulus frequencies. It will be noted below, using some examples, that hair cell micromechanics can be changed in a graduated fashion to produce frequency-response patterns that vary gradually over space (generally along a hearing organ, e.g., a phenomenon known as a tonotopic organization).

In many auditory organs (see below), the frequency response of the hair cells is largely determined by the stiffness of the bundle and the mass of the tectorial membrane. In lizards, the evolution of auditory organs was largely independent in different families and in some families, the tectorial mass over many of the hair cell bundles has been lost, but this loss of mass has been compensated for by an increase in bundle height and a reduction in stereovillar number of the bundles (see below and Manley, G. A., 2002; 2004). Of course, the type and number of transduction and other membrane channels in the outer and inner segments of the cell also play an important role in determining the cells' response characteristics. In some cases, as in turtle and bird auditory organs (see below), changes in the number, structure, and kinetics of membrane channels have been shown to strongly influence the gradient of the tonotopic organization (review in Köppl, C. *et al.*, 2000). Not surprisingly, variability in all of these features has produced a great variety of

morphological types and corresponding physiological responses. The following sections describe some of this diversity in different animal groups and different sensory epithelia.

3.01.3.2.2 Lateral-line hair cells of fish and Amphibia

Canals in dermal bone indicating the presence of an extensive lateral-line system have been described in the earliest of craniate fossils, in the jawless fish or ostracoderms (Carroll, R. L., 1987). Although there is no way to be sure what the sensory cells looked like, the structure of these canals, their distribution on the body (seven pairs in modern fish), and their innervation patterns indicate that they are homologous to the lateral lines of fish. Here, vertebrate-typical hair cells occur in groups that almost always have their stereovillar bundles embedded in sail-like tectorial masses called cupulae. Except in agnathans, both afferent and efferent fibers (the latter absent in agnathans, Görner, P., 1987) innervate typical hair cells.

There is evidence that the earliest hair cells occurred in groups associated with supporting cells in so-called neuromasts that were scattered in pits over the surface of the body, face, and mouth (Denison, R. H., 1966). This complexity was reduced very early by concentrating most or all of the neuromasts in a small number of canals with openings to the outside, most canals occurring on the animal's head. Such neuromast systems are found in all groups of modern fish and in the aquatic stages of amphibians, although in lampreys, slowly swimming, bottom-living fish and in amphibians, the neuromasts tend to lie in superficial pits rather than be sunken in canals (Young, J. Z., 1981). The lateral-line system is supposed to have given rise to electrosensory cells in at least two separate evolutionary events (Görner, P., 1987; Gibbs, M. A., 2004) and may also even be related to other secondary receptor cell systems such as taste cells (Smith, H. M., 1960). The origin of the lateral-line system as such must be sought in the earliest craniates, since only these have the dorsolateral placodal tissue from which this system (with few exceptions in amphibians) arises during ontogeny (Gibbs, M. A., 2004).

In a typical neuromast, the hair cells are arranged such that their bilaterally symmetrical stereovillar bundles show either of two orientations that are 180° opposed to each other. Thus these two groups of cells have their sensitive axes pointing in exactly opposite directions. Thus when one group of cells is stimulated, the other is not or even suppressed. Indeed, since these hair cells tend to be spontaneously active (indicating that at rest, their transduction channels have a significant opening probability), one population of hair cells would increase, the other decreasing its activity in response to the same stimulus. Neuromast hair cells respond with great sensitivity to displacement of the water over them and these responses provide information about the animal's own movements, the movements of other nearby organisms, and the presence of structures in the water (reviews in Flock, A., 1967; Russell, I. J., 1976; Sand, O., 1984; Bleckmann, H., 1986). There appears to be several stages in the evolution of lateral-line patterns and development in fish and amphibians (Pichon, F. and Ghysen, A., 2004).

Although hair cells in lateral-line neuromast systems tend to look similar to each other, there are few detailed studies of their fine structure and, given their different locations on the body, in canals, or on the surface, it would be surprising if specializations had not occurred. It is possible that the lateral-line mechanoreceptors of primitive hagfish resemble an early evolutionary stage of hair cell development, since they lack true stereovilli, their cilium being surrounded by microvilli and the cells lack polarization. It is, however, also possible that these cells in hagfish are degenerate. Lamprey lateral-line cells resemble typical hair cells but usually the neuromasts lack a cupula (review in Gibbs, M. A., 2004). In one study of the sensitivity of lateral-line hair cells to gentamicin that can destroy hair cells in hearing systems, hair cells in canal neuromasts were shown to be sensitive to gentamicin, whereas superficial hair cells were not (Song, J. *et al.*, 1995), indicating some kind of specialization. Since gentamicin acts through its ability to interact with the transduction channels, this suggests that the channels differ in some way between different groups of lateral-line hair cells, as has been noted in vestibular systems of vertebrates (Coffin, A. *et al.*, 2004). In addition, structurally differentiated types of hair cells that may correspond to different hair cell types found in vestibular organs have been demonstrated in a study of the lateral line of the ratfish (Ekström von Lubitz, D. K. J., 1981).

3.01.3.3 The Origin and History of Vestibular Systems in Craniates

A primitive vestibular organ was present in the earliest craniates, the ostracoderms (Carroll, R. L., 1987). Modern hagfish have one semicircular canal and lampreys have two (the anterior and posterior lateral

canals), as did the ostracoderms. It is possible that some ostracoderms had three or more, but the orientation of those canals did not allow for their preservation as fossils (Carroll, R. L., 1987). In addition to the sensory epithelia in these canals, agnathans only have a single additional area of sensory hair cells, the macula communis. The structural pattern typical for the vestibular organ of vertebrates, with three semicircular canals and two large spaces, the sacculus and utriculus, each with its own macula that can be supplemented by additional sensory organs in pouches (e.g., the lagenar macula) that arise from these spaces, obviously developed early in the evolution of the gnathostome fish (Figure 4; for details of the variety of organs and references, see Lewis, E. R. *et al.*, 1985). It appears that the sensory epithelium of the macula communis has been repeatedly and perhaps independently subdivided during the long evolutionary history of gnathostome vertebrates (Fritzsch, B. *et al.*, 2002).

3.01.3.3.1 The structure and diversity of the vestibular organ

In the semicircular canals, hair cells are restricted to so-called cristae in the terminal ampullae, where there is a cupula covering all hair cell bundles. In the sacculus and utriculus, there are – often large – sensory epithelia known as maculae and here, the hair cells are covered by an otolithic membrane. Other sensory epithelia (such as the macula neglecta and the macula lagenae) are generally small and carry otolithic membranes. All of these organs consist of sometimes very large hair cell epithelia that sit on a firm substrate (Lewis, E. R. *et al.*, 1985).

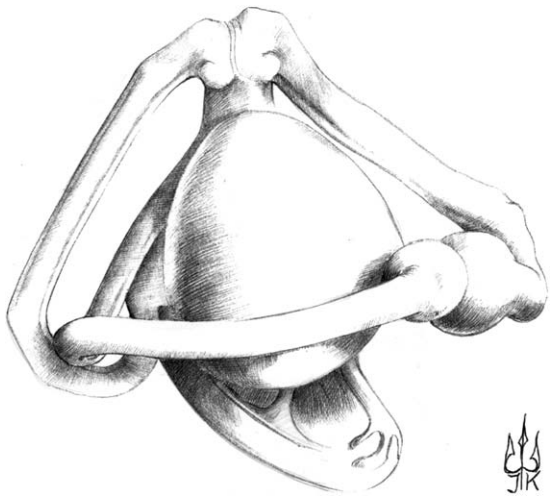

Figure 4 A schematic drawing of a typical vestibular organ of a vertebrate, here from the Australian bobtail skink *Tiliqua rugosa*. The vestibular system is seen from the animal's right side. Dorsal is up and the view is from lateral. The large globe in the center is the sacculus. The three semicircular canals can be seen, as can some of their ampullae. The lagena lies ventrally and is partially obscured by the sacculus. In the lagena, the finger processes of the nerve to the lagenar macula can be seen (right), as can the fan-shaped nerve to the basilar papilla. An original drawing by Johanna Kraus, all rights reserved.

The cristae are sensory epithelia that are stimulated by head rotation that causes a displacement of the cupula due to the inertia of the endolymphatic fluid in the semicircular canals. All hair cell stereovillar bundles in a crista are oriented in the same direction but those of different cristae may be oppositely oriented. In contrast to the relative uniformity of the cristae, great variety exists in the number, size, shape, and degree of specialization of the sensory maculae of the vestibular systems of different vertebrates (Lewis, E. R. *et al.*, 1985). The specializations are obviously not confined to macroscopic structural changes, since changes in the electrical properties of hair cells have also been found. Both structural and membrane properties of the hair cells will exert powerful influences on their sensory response properties.

Vestibular sensory epithelia in amniote vertebrates, both cristae and maculae with otoliths in their covering membranes, tend to show two types of hair cells that are differently distributed throughout the epithelia (see Lewis, E. R. *et al.*, 1985 for references). The more primitive kind of hair cell is the so-called type II. It is a mostly cylindrical hair cell that makes small synapses with afferent and, less frequently, efferent nerve fibers. Type I hair cells are more globular or flask-shaped, with a narrow neck and widened apex above it, and are a characteristic of amniote vestibular systems. There is some evidence that, ontogenetically, type I hair cells begin life as type II forms (Masetto, S. and Carreia, M. J., 1997). Most of the type I hair cell is surrounded by a large nerve terminal, the calyx, that may also enclose other hair cells. Efferent fibers synapse on this calyx and not on the hair cell. Especially in mammals, intermediate cell forms are known. Most physiological studies of these two hair cell types have been carried out in mammals, resulting in the tentative conclusion that type I hair cells respond to stimulation faster, with increased gain for small stimuli and an expanded dynamic range, whereas type II hair cells may be more sensitive. The huge synaptic calyx of type I hair cells apparently contains reciprocal

synapses with the hair cell that are responsible for a feedback process within the calyx that can produce large responses rapidly (Devau, G., 2000).

Different hair cell types are not distributed uniformly throughout vestibular epithelia, but their patterns are species-specific (Lewis, E. R. *et al.*, 1985). In general, type I hair cells tend to be concentrated along the center of the epithelium. Especially in otolith organs, a centrally lying strip of hair cells known as the striola tends to contain mainly type I, whereas type II hair cells are more numerous toward the periphery. Within these two types of hair cells and in nonamniotes, which show little evidence of such pronounced hair cell specializations, there is still a great variety in hair cell form due, for example, to the size, shape, and height of the bundles and the precise arrangement of stereovilli in the bundles.

3.01.3.3.2 Auditory-vestibular sensory epithelia of fish

In both cartilaginous and bony fish, hair cells of diverse vestibular maculae mediate the senses not only of rotational and linear acceleration, but also of hearing (for refs see Popper, A. N. and Fay, R. R., 1999; Ladich, F. and Popper, A. N., 2004). Hearing apparently coexists with vestibular responses from end organs that may or may not be covered by an otolithic membrane and, in fish as a whole, there is a great variety in size and structure of the various end organs between and even within systematic groups. The vestibular maculae display a variety of different hair cell orientation patterns, which are believed to contribute to the abilities of those fish to localize sounds (Fay, R. R. and Edds-Walton, P. L., 1997; Lu, Z. and Popper, A. N., 2001). In addition, in some fish groups, hearing sensitivity is improved by additional structures such as the Weberian ossicles to the swim bladder.

Although fish vestibular hair cells show no overt evidence of specialized cell types, such cells do have different arrangements of the kinocilium and stereovilli in their bundles (for references see Coffin, A. *et al.*, 2004). The columnar shape of the hair cells resembles the type earlier defined in amniotes as type II. However, biochemical studies using a calcium-binding protein and antibiotic agents revealed the presence of two types of hair cells with a differential distribution in the organs. Hair cells in different areas of fish maculae also show clear differences in their physiological response patterns. This suggests that during vertebrate evolution, hair cell specialization in terms of cell-membrane channels and other proteins, for example, began before obvious morphological specialization.

For agnathan fish, auditory function has not been localized to one of the various vestibular epithelia, and auditory function is poorly understood in cartilaginous fish (where the macula neglecta, lagena, and utricle may all play a role). However, it is well understood in bony fish (Ladich, F. and Popper, A. N., 2004). Whereas in these animals the utricular macula, with few exceptions, is relatively uniform, the saccular and (in fewer species) the lagenar macula vary greatly in size. There is evidence that this variety is linked to a function of these epithelia as both vestibular and auditory organs. The function of hearing is based on the sound in water moving the entire fish, whereby the denser otolithic material tends to lag in phase and therefore stimulate the underlying hair cells. In some groups, the frequency response goes up remarkably high, to several kilohertz, and the frequency responses may be spread systematically on the sensory epithelium. The latter implies a highly organized epithelium, with the properties of individual hair cells (presumably both structural and biochemical) varying systematically from place to place.

3.01.3.4 The Origin and Phylogeny of a Dedicated Auditory Epithelium

The dedicated auditory receptor of land vertebrates, the first epithelium in vertebrate evolution that responded exclusively to sound, is called the basilar papilla. It developed, like many vestibular epithelia, as an out-pocketing from the saccular macula. There is evidence that such an epithelium is present in the coelocanth *Latimeria* (Fritzsch, B., 1992) and thus by inference in the sister group of the ancestors of land vertebrates. It is, however, uncertain whether this was a unique event for all lobe-finned fish and their close relatives or whether *Latimeria* ancestors developed this epithelium independently of the true ancestors of land vertebrates. One of the difficulties with the assumption of an originating event in the common ancestor of lobe-finned fish and land vertebrates is the situation encountered in modern amphibians, where neither of the two auditory epithelia is conclusively considered to be homologous to the amniote basilar papilla. Thus either the ancestors of the Lissamphibia lost the basilar papilla and later developed their own two auditory organs or the *Latimeria* epithelium does not indicate that the basilar papilla of amniotes can be traced back to the

lobe-finned fish. Using the second possibility, this would mean that the amniote basilar papilla arose in the ancestors of the stem reptiles.

3.01.3.4.1 The hearing organs of amphibians (frogs and toads and their relatives)

In an extensive review of amphibian hearing mechanisms, Smotherman M. and Narins P., (2004) state that "Differences in the physiology of hearing can be seen within every branch of the amphibian phylogenetic tree, and range from such gross morphological differences as the absence of a middle ear down to subtle differences in hair cell stereovillar architecture." Considering this great diversity, we will ignore the middle ear and morphology of the endolymphatic system (that show important differences to the amniotes, Smotherman, M. and Narins, P., 2004), and restrict our discussion here to the specializations of the hair cells in the hearing organs of amphibians.

As noted above, modern amphibians, which are considered to be a monophyletic group, in addition to the retention of some acoustic sensitivity of the sacculus as in most fish, usually have two hearing epithelia, known as the basilar and the amphibian papillae. In contrast to the amphibian papilla, the basilar papilla is not found in all groups of Amphibia. The amphibian papilla is not considered to be homologous to the amniote basilar papilla, whereas there is considerable discussion as to whether the basilar papillae of amphibians and amniotes are homologous (for a review see Smotherman, M. and Narins, P., 2004). If the basilar papilla is a homolog, it has lost many of the structural (e.g., the freely moving basilar membrane) and functional characteristics of the amniote basilar papilla (i.e., the hair cell specialization and tonotopic organization).

The amphibian papilla probably originated as an outpocket near the duct joining the utriculus and the ventrally lying sacculus. It varies greatly in its structure throughout the amphibians. In some amphibian lineages, the amphibian papilla, with its tectorial membrane, is elongated and equipped with many more hair cells. At the distal end of the papilla there is a so-called contact membrane that permits pressure waves to leave the surrounding space, enabling sensitive responses to sound. The most primitive amphibian papilla is probably that seen in urodeles and the most primitive anurans and is a small patch of sensory hair cells located on the dorsomedial wall of the recess. More advanced anuran amphibians have a caudal extension to the sensory epithelium, the length of which correlates with an increase in the frequency-response range processed by this papilla (Smotherman, M. and Narins, P., 2004).

The basilar papilla of amphibians is found in all frogs, some salamanders, and a minority of caecilians. It contains a very small patch of 50 or so hair cells located beneath a thin tectorial membrane, the latter being stretched across the recess of the basilar papilla. Behind the sensory epithelium lies a contact membrane separating the recess from the periotic space. The basilar papilla is anatomically very uniform in all amphibian groups, but its exact location varies between the groups. In strong contrast to the hair cell array of the amphibian papilla (and indeed to hearing epithelia of amniotes), all the hair cells of the basilar papilla of the amphibians respond to a single, narrow frequency range that is species-specific. The basilar papilla thus appears to be a simple resonant structure (Meenderink, S. W. *et al.*, 2005) and it would not be expected that the hair cells would differ from one another in any pronounced way.

The amphibian papilla, by contrast, shows specializations in different amphibian groups in the presence or absence of electrically tuned hair cells, in the characteristics of the hair cell bundles and in the hair cell orientation patterns. Electrical tuning of hair cells, known from the fish and amphibian sacculus, probably arose fairly early in the evolution of hair cells and provides an important mechanism for frequency selectivity at least for frequencies below about 1 kHz (review in Fettiplace, R., 1987; Manley, G. A., 2000). It is found in about half of the hair cells of the amphibian papilla and in a small percentage of hair cells from the basilar papilla, although the latter only show this resonance in a different frequency range to that of their acoustic responses. In electrically tuned hair cells of the amphibian papilla in the anuran *Rana pipiens*, the hair cell response frequencies are organized into a tonotopic spatial array in which the best response frequency of any given hair cell is partly determined by the number and the kinetics of particular membrane channels that vary systematically along the epithelium (Smotherman, M. and Narins, P., 2004). The electrical properties of the saccular and amphibian papilla hair cells are fundamentally similar, but in the amphibian papilla, additional structural gradients in the hair cells influence the range of best frequencies along the epithelium.

Hair cell orientation patterns in the anuran amphibian papilla and basilar papilla are diverse. Most basilar papilla hair cells are polarized in the same direction, as are hair cells of the amphibian

papilla in the Caudata and Gymnophiona. In the more derived anuran amphibians, however, the amphibian papilla exhibits a much more complex array of hair cell orientation patterns, but no functional correlates have yet been reported (Smotherman, M. and Narins, P., 2004).

3.01.3.4.2 The hearing organs of lepidosaurs (lizards and snakes)

The phylogeny of the lepidosaur hearing epithelium has recently been extensively reviewed and will thus only be summarized here (Manley, G. A., 2000; 2002; 2004). The snake auditory papilla is very simple in its structure and resembles that of primitive lepidosaurs (tuataras) and the presumably primitive hearing organs of turtles. It consists of an elongated array of up to 1000 hair cells that are all oriented in the same direction (Miller, M. R., 1978; Wever, E. G., 1978) and whose response frequencies, which reach up to about 1 kHz, vary systematically from low frequencies apically to the highest frequencies basally. Although in the turtle papilla, the tonotopic arrangement of frequency responses is known to be due to both hair cell stereovillar bundle structure and electrical tuning (see Manley, G. A., 1990 for references), there are no recordings from hair cells or from the auditory nerve of snakes.

Considerably more information is available on specializations of hair cells in lizards (reviews in Wever, E. G., 1978; Miller, M. R., 1992; Manley, G. A., 2004). In these animals, the auditory epithelium is unique among amniotes in that it is always divided along its length into at least two hair cell arrays in which the hair cells belong to two different types which respond to different frequency ranges. In one of these areas, the hair cells (for which Miller, M. R., 1992 used the term UDT or unidirectional type to describe their unique morphology) are almost always oriented in one direction (abneurally), receive both afferent and efferent nerve fibers, are always covered by a tectorial membrane, and respond to frequencies below 1 kHz. Although in this respect they resemble the entire turtle papilla, there is no evidence for a pronounced electrical tuning of these lizard hair cells.

The other hair cell array consists of hair cells (Miller, M. R., 1992 referred to these as BDT or bidirectional type) which are generally in groups that have their bundles oppositely oriented (Figure 5) and have only an afferent innervation. Their response frequencies lie higher than 1 kHz and generally up to 5 kHz, in some cases higher. These hair cells may or may not be covered by a tectorial membrane, which

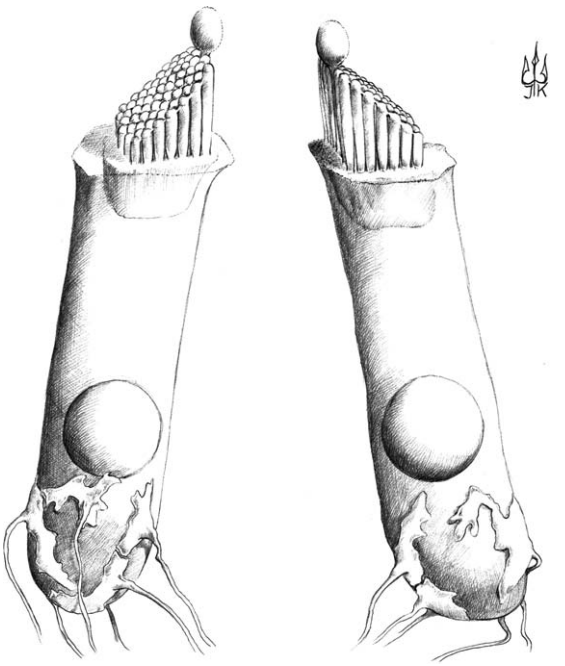

Figure 5 A schematic drawing of hair cell orientation pattern in lizards. In this figure, two hair cells are shown from the high-frequency area of a lizard papilla to illustrate the opposite orientation of the stereovillar bundles. In the species illustrated here (a lacertid lizard), the kinocilia are bulbed at their tips. Such high-frequency hair cells are micromechanically tuned and receive only an afferent innervation. An original drawing by Johanna Kraus, all rights reserved.

can take different forms. The response properties of these two hair cell populations differ not only in their frequency ranges but also in their intensity function patterns and their ability to phase lock to sinusoidal sound stimuli (Köppl, C. and Manley, G. A., 1990; Manley, G. A. *et al.*, 1990; Eatock, R. A. *et al.*, 1991; Manley, G. A., 2004).

It is likely that the plesiomorphic lizard basilar papilla contained three hair cell areas, one central area of UDT hair cells flanked at both ends by areas of BDT hair cells that were mirror images of each other (Manley, G. A., 2000; 2004). In some of the various families of lizards, one of these areas was lost (presumably because, being mirror images, one of them was redundant). In different lizard lineages, either the apical or the basal area was lost (Manley, G. A., 2002); in snakes, both areas were lost. Since the BDT areas respond to higher frequencies, primitive lizard papillae have a curious tonotopicity in which the cell response frequencies increase toward the two ends of the papilla. Where the apical high-frequency

area was lost, the tonotopicity resembles that of most other amniotes, increasing steadily toward the basal end of the papilla (Manley, G. A., 2000). Where the basal BDT area was lost, as in geckos, the tonotopicity is, as expected, reversed, a unique situation among amniotes (Manley, G. A. *et al.*, 1999).

It thus appears as if the specializations of hair cells in lizards vary between the plesiomorphic (for stem reptiles) UDT area, which in its properties continues in the long tradition established in the saccular macula. The BDT hair cells are almost unique among amniotes in their total loss of the efferent innervation (some specialized regions of some bat cochleae show this phenomenon). The BDT hair cell area(s) that are an apomorphy of lizards consist of hair cells that do not use electrical tuning, but instead perfected the mechanism of frequency selectivity known as micromechanical tuning. In such cells, the frequency selectivity results from the precise mechanical properties of the hair cell bundles (such as the bundle stiffness) and of the structures that surround them, such as the mass of the tectorial membrane (Figure 6). Precise and location-specific variations in these properties, often in groups of hair cells that are coupled, are the basis for the tonotopic organization. Knowledge of these gradients makes it possible to model the frequency-response limits and gradient (e.g., Manley, G. A. *et al.*, 1989). Since the basilar membrane in lizards is not tuned to different frequencies along its length (see Manley, G. A., 1990 for references), all of the frequency selectivity must originate in the hair cells and, if present, their local tectorial structure.

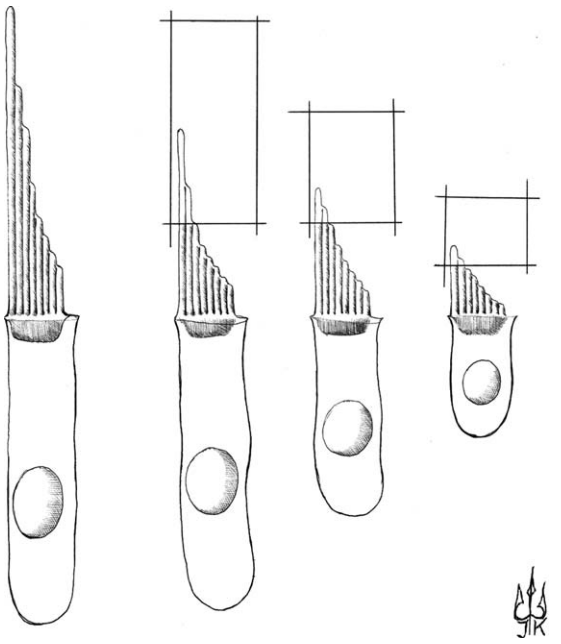

Figure 6 A schematic drawing of four hair cells to illustrate the principal structural changes underlying micromechanical tuning in the high-frequency hair cell areas of lizard auditory papillae. The hair cell on the left has no tectorial structure and this is associated with tall stereovillar bundles. The three cells to its right each carry a tectorial structure, which is shown highly schematically as if isolated, but could be part of a continuous tectorial membrane or of a local salletal unit. The mass of the tectorial structure and the bundle height vary systematically along the papilla and are responsible for the gradual change in the preferred response frequency of the hair cells. In this case, the frequency would rise from left to right hair cells. An original drawing by Johanna Kraus, all rights reserved.

3.01.3.4.3 The hearing organs of archosaur groups (dinosaurs, crocodilians, birds)

The evolution of the auditory epithelium of archosaurs has recently been reviewed (Gleich, O. *et al.*, 2004) and will therefore only be discussed here with reference to hair cell specializations. A comparison of the inner ears of the group of crocodilians with those of modern birds and an examination of recent fossil findings of casts of the inner ears of dinosaur groups have made it possible to speculate that the archosaur inner ear originated early in their lineage and is an apomorphy of the entire group. The hearing epithelium is elongated, up to 11 mm in length. It differs from that of lepidosaurs on the one hand and mammals on the other (both groups in which hair cells tend to be arranged in rows along the papilla) in that the hair cells and supporting cells form irregular mosaics. In addition, the width of the papilla can be large and there may be up to 50 hair cells in any transverse section of the wider, apical end of the epithelium. This contrasts with the 4–6 hair cells seen across the width of the papillae of lizards and mammals. Thus, although on average the avian and crocodilian papilla may be shorter than that of mammals, the number of hair cells can easily be as large or larger. In addition to the above, the archosaur epithelium is not all arrayed over the freely moving basilar membrane; instead, a substantial proportion of hair cells lies over the neural limbus, a firm and thick structure. It is thus apparent that the tectorial membrane, which is thick and covers all hair cells, surrounding their bundles in dome-like, individual concavities, plays a critical important role in hair cell stimulation (Manley, G. A., 1995).

The archosaur auditory papilla is also characterized by substantial gradients in different planes and in different structural and molecular features. It is presumed that together, these micromechanical and electrical features create the tonotopic organization of the papilla (Gleich, O. *et al.*, 2004). There are clear morphological gradients, such as in the mass of the tectorial membrane, the height and width of the hair cells, the height of their stereovillar bundles, and the number of stereovilli per bundle and the pattern of innervation (Figure 7). At the extremes, apical, neurally lying hair cells are very tall, their bundles have relatively few stereovilli that are tall and covered by a thick tectorial membrane. They receive both afferent and efferent innervation. At the other extreme, basal, abneural hair cells are much shorter, their bundles have 5–6 times as many stereovilli that are short and covered by a thinner tectorial membrane. These cells are only efferently innervated (Fischer, F. P., 1994; Gleich, O. *et al.*, 2004). In crocodilians, there tends to be a more sudden change from the one hair cell type to the other across the papilla.

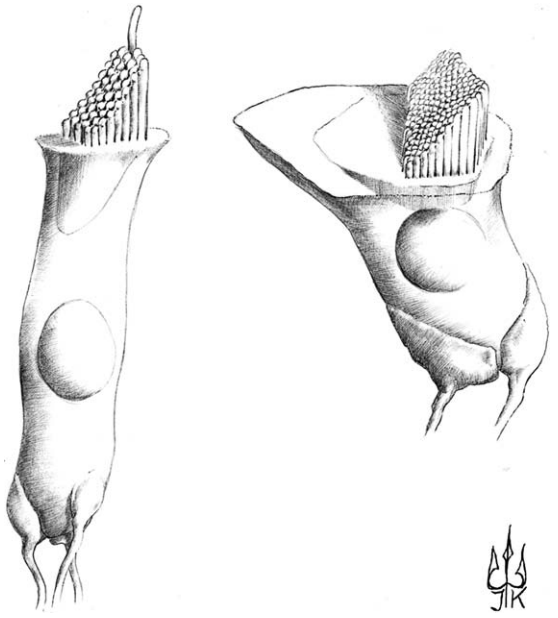

Figure 7 A schematic drawing of hair cell specializations in birds. These two hair cells illustrate the extremes of the structural differences shown by hair cells across and along the avian auditory papilla. On the left is a tall hair cell, which is both afferently and efferently innervated. The cuticular plate tends to go deeply into the cell. Such tall hair cells are typical for apical and neural hair cell areas. On the right is shown a short hair cell that is only efferently innervated. The apical surface of this cell is tilted somewhat toward the observer in order to more clearly show the broad, toothbrush-like, stereovillar bundle structure. Such short hair cells are typical of basal and abneural hair cell areas. An original drawing by Johanna Kraus, all rights reserved.

In addition and parallel to these morphological gradients, there are systematic changes in the molecular constituents of the cell membrane in various positions on the papilla, especially in those ion channels that are involved in electrical tuning (see, e.g., Rosenblatt, K. P. *et al.*, 1997; review in Köppl, C. *et al.*, 2000). The number and kinetics of K_{Ca} channels, which vary in their calcium and voltage sensitivities, are differentially distributed along the papilla, strongly suggesting that they also contribute to the tonotopic frequency arrangement. Alternative splicing can potentially generate thousands of ion-channel phenotypes that, combined with variations in calcium sensitivities, modulation by β subunits, and differing channel numbers per cell, would easily account for a large range of frequency responses. The avian auditory papilla provides one of the most interesting examples of genetic flexibility that creates a wide spectrum of functional variations within one type of cell.

The gradients described and the patterns of bundle orientation produce an exactly tonotopically organized auditory epithelium, with the lowest frequencies apically and the highest basally. There is also evidence that the tall hair cells lying over the neural limbus are more sensitive than hair cells lying further abneurally, with, in the starling, a change of 6 B per hair cell across the epithelium (see Gleich, O. *et al.*, 2004 for references). The expected change of hair cell sensitivity due to rotation of the bundle toward the middle of the papilla is compatible with these data, as is the fact that abneurally lying hair cells are not even afferently innervated. It is possible that abneural, short hair cells function as amplifiers in a similar way to the outer hair cells of mammals.

3.01.3.4.4 The hearing organs of mammals

With the exception of the egg-laying monotreme mammals, the auditory epithelium of mammals is coiled helically with the neural side on the inside of the helix. The hair cells are generally strictly arranged in rows, with a single row of inner hair cells and, except at the apex in some groups, three rows of outer hair cells (Figure 8). This specific arrangement, which is common to both placental and marsupial mammals, likely arose after their separation from the monotreme mammals that have

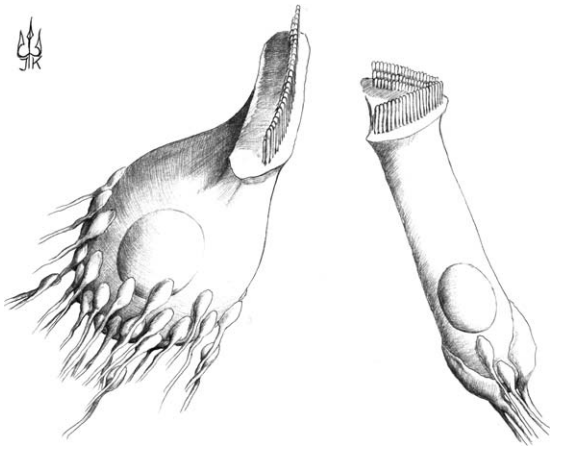

Figure 8 A schematic drawing of hair cell specializations in mammals. The two distinct hair cell populations of the mammalian cochlea are illustrated in this figure. On the left is a typically bulbous inner hair cell that is innervated by a large number of afferent fibers, which in turn receive synapses from a few efferent fibers. Its bundle is straight and made up of only a few rows of stereovilli. The outer hair cell on the right is typically cylindrical and mainly, but not exclusively, innervated by large efferent endings. Its bundle has a W shape, where the angle between the long arms of the W can vary with position along the cochlea. An original drawing by Johanna Kraus, all rights reserved.

more rows of both inner and outer hair cells (for references see Vater, M. *et al.*, 2004).

Inner hair cells are somewhat globular in shape, enclosed by supporting cells, and innervated by large numbers (15–30) of afferent nerve fibers that themselves (but seldom the hair cells) are efferently innervated. The hair bundle of inner hair cells contains only a few rows of stereovilli, and the bundle stands parallel to the long axis of the epithelium. Outer hair cells are more columnar in shape and their basal areas lie free in the fluid of Corti's organ. Their bundles contain more stereovilli and are in general arranged in a W-shape, with the open side of the W roughly pointing toward the inner hair cells. Outer hair cells, although numerically about 80% of all cochlear hair cells, are only innervated by 5–10% of the afferent nerve fibers, most of their basal synaptic area being contacted by large efferent endings (Spoendlin, H., 1978). There is much evidence that, in convergent evolution to the archosaur papilla, outer hair cells have a reduced afferent innervation because their main function is within the hearing organ, amplifying weak sounds. The resulting stimulus is then detected and transmitted to the brain via the inner hair cells.

This clear and profound specialization into two hair cell types that has been described in both birds and mammals is the clearest case of extreme differences between hair cell groups that has been observed in vertebrates. It exists at the same time as the general presence of gradients in both hair cell types along and across the papilla that determine, for example, their frequency responses and thus the pattern of the tonotopic organization.

3.01.3.5 A Synopsis of Hair Cell Phylogeny in Vertebrates

It is likely that the first vertebrate hair cell organs were lateral lines that contained a single type of hair cell. With differentiation of the lateral line into different types of organs, hair cell specialization set in as a result of selection pressures to better analyze the sensory information offered by the environment. Similarly, the analysis of stimuli by semicircular canal cristae and vestibular maculae depended not only on canal dimensions and the characteristics of the otolithic masses overlying the maculae, but also on hair cell differentiation. During the evolution of fish, the fundamental specialization of vestibular hair cells into two types began with minor structural and biochemical changes, but this became much more pronounced in the land vertebrates, where the two types are easily recognizable via overt structural features. Although it is likely that the hearing organs of land vertebrates began by utilizing only type II hair cells, unique kinds of hair cell specializations arose in lepidosaur, archosaur, and mammal ancestors that are recognizable along and across the respective epithelia. These generally show functional specializations at least as profound as their differing structural features to the extent that in birds and mammals at least, the functions of stimulus detection and stimulus amplification have been separated by a division of labor between two populations of highly specialized hair cells.

3.01.4 Ciliated Mechanoreceptors of Nonchordate Animals

Ciliated mechanoreceptors are found even in the earliest of Eumetazoa; however, the consideration of their homology with vertebrate auditory hair cells is not trivial. As we have already mentioned, considerations of homology can be made using comparative anatomy, which are qualitative (a structure

is either homologous or not), or can be made using molecular biology using sequence comparisons that are quantitative. As data exist on both anatomy and molecular biology, both aspects need to be considered. In this section we primarily focus on describing the anatomy of ciliated mechanoreceptors from a sampling of nonchordate groups, starting from the most primitive, the cnidarians, and progressing to ecdysozoans as exemplified by the nematode and dipteran insects and the lophotrochozoan cephalopod mollusks. We describe the structural characteristics of the ciliated mechanoreceptor found in these groups and discuss the molecular correlates that are known. While it is possible that an archetype for the ciliated mechanoreceptor is present (Vinnikov, Y. A., 1982), its significance must be placed within the context of the phylogeny (Adoutte, A. *et al.*, 2000).

In most cases the ciliated sensory neuron is of the primary type, that is, it can be thought of as a bipolar neuron, with its own axon. Secondary ciliated sensory neurons, seen in coelid cephalopod mollusks and in vertebrates, are modified epithelial cells and do not have axons.

3.01.4.1 Cnidarian Hair Cells

Cnidarians, the group containing hydra, jellyfish, and sea anemones, are basal eumetazoans positioned before the radiation of metazoans into deuterostomes and protostomes. This location highlights the importance of the cnidarians in any evolutionary discussion. Cnidarians do possess ciliated mechanoreceptors, responsible for both touch sensation and gravity sensation; they also show morphological variation depending not only on species but also on the function within an individual. In cnidarians, ciliated mechanoreceptors are found in specialized orientation organs, and also serve a combined chemosensory and mechanosensory role in the various types of stinging cell, the nematocysts.

The cnidocyte is a unique and defining feature of the phylum Cnidaria, playing a role in prey detection, capture, and defense (Ruppert, E. E. *et al.*, 2004; Figure 9). A cnidocyte itself houses a large fluid-filled sac, a cnidae which itself contains a large inverted tubule. Upon appropriate stimulation, the tubule is rapidly everted and penetrates the prey, in many cases concomitantly releasing toxin that causes stinging or paralysis. Three types of cnidocytes have been identified; two of them, spirocysts and pthychocysts, are only found in the class Anthozoa (corals, sea anemones, sea ferns, and sea pens); indeed

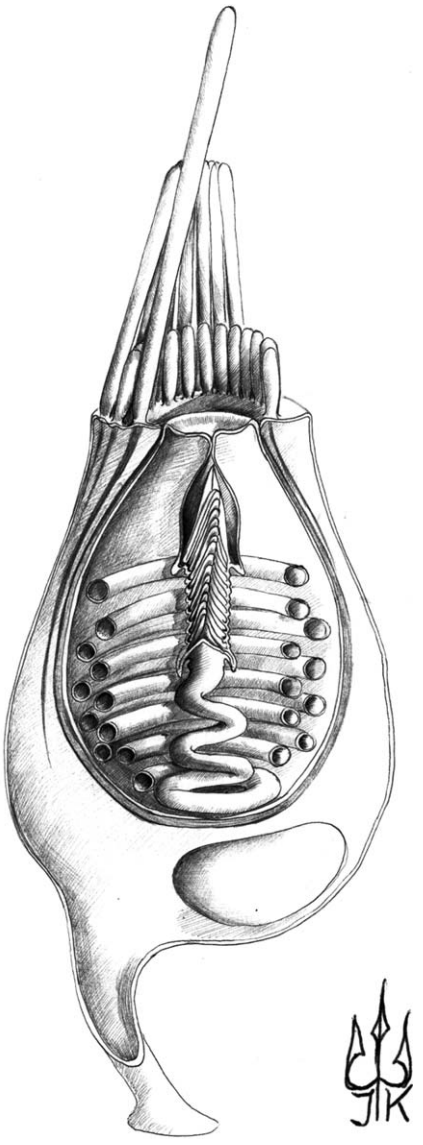

Figure 9 A schematic drawing of a nematocyte of the Cnidaria. These cells are connected synaptically at their base to nerve cells and/or epithelial muscle cells. Within the cell is the nematocyst, a capsule containing a thread that can be rapidly discharged into the prey. An original drawing by Johanna Kraus, all rights reserved.

pthychocysts are only found in the epidermis of the tube anemone. The third type of cnidocyte is the nematocyst, found throughout the cnidarian phylum and, for our purposes, the most interesting. These are associated with supporting cells.

The nematocyst itself is part of a type I sensory neuron and bears a sensory cilium. In anthozoans (sea anemones and corals), the cilium is motile (and called a ciliary cone) whereas in hydrozoans and

scyphozoans it is nonmotile (and called a cnidocil) (Peteya, D. J., 1975; Holstein, T. and Hausmann, K., 1988). The ciliary cone consists of a long cilium with a typical 9×2 (these are the peripheral doublets of A and B microtubules) +2 (a central pair of microtubules) configuration of microtubules, a common feature of sensory cilia (Vinnikov, Y. A., 1982). The cilium is surrounded by large diameter stereovilli of shorter length than the cnidocil itself, which are in turn surrounded by a palisade of shorter, smaller diameter stereovilli from the adjacent cells, the supporting cells (Peteya, D. J., 1975). The numbers of these larger and small stereovilli can vary; however, all seem to be stiffened by actin filaments (Wood, R. L. and Novak, P. L., 1982; Stidwill, R. P. *et al.*, 1988).

The resemblance of the sensory apparatus of the nematocyst to the hair cells of vertebrates suggests a mechanosensory function of these cilia, and indeed some data indicate that this is the case. Using a loose-patch, cell-associated recording method in slices of anemone tentacles, Mire and Watson measured the electrophysiological changes of the hair bundles of the nematocyst under mechanical stimulation (Mire, P. and Watson, G. M., 1997; Watson, G. M. and Mire, P., 1999). When the hair bundles were deflected using puffs of seawater, changes in membrane potential were recorded. Some cells were hyperpolarized in a graded manner, while others depolarized, depending on the direction of the deflection. By plotting the response amplitude as a function of the deflection magnitude, it became clear that the negative response is smaller and saturates relatively easily, whereas the positive response is larger and saturates more gradually, a characteristic of other mechanotransducers such as hair cells of the vertebrate inner ear (Hudspeth, A. J. and Corey, D. P., 1977). Indeed the presence of tip links in the nematocyst hair bundle may suggest that a process common to the vertebrate hair cell and involving a mechanically gated ion channel is responsible for mechanoreception (Watson, G. M. *et al.*, 1997).

Ciliated mechanoreceptors do not occur just in nematocysts; hydrozoan, scyphozoan, and cubozoan species also have a gravity-sensing organ known as the statocyst (Horridge, G. A., 1969). As shown by statocyst ablations in the hydrozoan *Aequorea*, this organ is responsible for the righting behavior of the animal (Singla, C. L., 1975). There is a huge variety of statocysts in the cnidarians, even within those of the same class; however, they all have a cell, the lithocyte, which contains a large concretion of some calcium salt (Horridge, G. A., 1969). The weighted lithocyte is deflected when the position or equilibrium of the animal is altered. Ciliated sensory cells that surround the concreted cell register this deflection. These ciliated cells are type I sensory cells, that is, cells that have a distal cilium and a proximal axon (Horridge, G. A., 1969). There are three types of ciliated sensory cells found in the cnidarian statocysts that have been examined. Leptomedusae typically have a single kinocilium and lack associated stereovilli. In Narcomedusae and Tracymedusae the sensory cells bear a kinocilium that is surrounded by a ring of stereovilli (Singla, C. L., 1983). The third type of ciliated sensory cell is found in a subset of statocysts in the basal cushion and sensory papilla. The kinocilia are extremely long and stiff with a well-developed rootlet system extending into the cytoplasm.

While the cytomechanics of nematocyst hair bundle function are beginning to be characterized, little work has been performed on the cytomechanical function of the cnidarian statocyst mechanoreceptor. Although it is likely that a mechanism consistent with the gated-channel model also functions in the statocyst hair cells of cnidarians, until the electrophysiology is investigated and until the molecular candidates are known, any proposed mechanism remains speculative.

3.01.4.2 Mechanotransduction in *Caenorhabditis elegans*

The nematode worm *C. elegans* has been used extensively as a model organism for developmental biology. The lineage of each individual cell has been traced and, when combined with the genetic tractability of the animal, has led to an understanding of the interactions that specify these lineages. *C. elegans* hermaphrodites are known to have 302 neurons, and a number of them are responsible for different mechanosensory behaviors: the gentle body touch, the harsh body touch, the nose touch, and a response to texture (Ernstrom, G. G. and Chalfie, M., 2002). As the neurons that mediate both the harsh and gentle body touch are not ciliated and detection appears to be mediated by varicosities, these will not be considered further (Chalfie, M. and Thomson, J. N., 1982; Chalfie, M. *et al.*, 1985).

There are some behaviors in *C. elegans* that are mediated by ciliated mechanosensory neurons. One is the nose touch avoidance, which causes the worm to move back if it bumps its anterior pole (Kaplan, J. M. and Horvitz, H. R., 1993). This behavior is mediated by

a number of sensory neurons, named ASH, FLP, and OLQ. The ASH neurons are mono-ciliated type I sensory neurons. Perkins, L. A. *et al.*, (1986) describe three segments to the cilium. The proximal zone, found at the base of the cilium, consists of 9×2 microtubules attached to the membrane by Y-shaped links arranged around a central cylinder. This cylinder contains a core of a variable number of singlet microtubules. Further distally, in the transition zone, there is no central cylinder, although the odd singlet microtubule can be seen. The peripheral microtubules spread apart, causing an apparent loss in the doublet structure and indeed the B subfibers are gradually lost toward the distal segment, the end of the microtubule. This, in effect, causes the cilium to flare, becoming thicker distally. The other neurons of this pathway, the FLP and OLQ neurons, rather resemble the CEP and ADE neurons which are described below.

The CEP and ADE neurons mediate a behavior related to texture sensation that indicates food (Sawin, E. R. *et al.*, 2000). When the worm encounters a bacterial lawn on an agar substrate, it slows down, presumably to dwell for longer so it can ingest more food. This behavior can be mimicked using sepharose beads and so it is likely that this slowing behavior is due to mechanoreception and not chemosensation. Indeed these cells express the worm homolog of the mechanotransduction channel found in *Drosophila* sensory bristles, *NompC* (Walker, R. G. *et al.*, 2000). The neurons themselves (i.e., the CEP, ADE, FLP, and OLQ) are mono-ciliated type I sensory neurons. The transition zone in their cilia resembles that of the ASH cilium, with 9×2 peripheral microtubules arranged around a central core (Perkins, L. A. *et al.*, 1986). However, some of these doublets terminate just distal to the transition zone. There is some variety in the characteristics of the distal segments of these neurons. For example, in the CEP cilia, the microtubules are interspersed with an electron-dense material and mold them into irregular rods. In OLQ neurons, the cores of the microtubules making up the doublets are filled. Both the CEP and OLQ neurons are anchored into the cuticle of the worm using a small nubbin, a varicosity on one side of the cilium, at the base of the transducing region.

An interesting property of the texture sensation behavior is its modulation depending on whether the animal is satiated or starved. This depends on serotonin and has provided some insights into the mechanisms by which neuromodulation can impact on mechanosensation (Sanyal, S. *et al.*, 2004). These kinds of studies highlight the strength of *C. elegans* for studies into neuromodulation. Synaptic contacts have been found on the CEP neurons from the neurons mediating the gentle touch (Chalfie, M. *et al.*, 1985). It is thought that encountering bacteria may register as a gentle touch (causing the animal to stop); by direct neurological input, the gentle touch response is abrogated when the animals encounter bacteria.

While *C. elegans* is a good model for the modulation of mechanosensation and the mechanisms by which other modalities can impact mechanoreception, there is still no clear mechanism as to how the mechanosensory transduction channels respond to vibrations, and indeed none that conforms to the gated-spring model proposed for hair cell stereovilli. One conjectured model could be similar to that proposed for *Drosophila* mechanotransduction (see below). Here NompC on the sensory neuron is attached to NompA anchored on a supporting cell. While NompC is found on mechanosensitive CEP neurons, a *C. elegans NompA* homolog has not yet been characterized.

3.01.4.3 Ciliated Mechanoreceptors in Insects

Insects have three basic types of ciliated mechanoreceptor: the bristle organ, the campaniform sensillum, and the chordotonal organ (Keil, T. A., 1997). All of them share common features, although they have become elaborated for their particular functions. The basic structure of what has been termed the organule is a central type I ciliated sensory neuron innervating a structure formed by three support cells (Lawrence, P. A., 1966). The cilium of the sensory neuron can be separated into two distinct domains. The cilium itself starts just above the distalmost centriole in the neuron and is initially of the $9 \times 2 + 0$ type. As the cilium extends distally, it may flare out, increasing in diameter and in the number of microtubules. At its most distal point the cilium contains a highly ordered cytoskeletal complex, the tubular body. This is made of a few to many thousands of short microtubules tightly packed into an electron-dense structure (Keil, T. A., 1997). This is attached to the membrane via various connectors, which is in turn attached to the dendritic cap, an extracellular matrix (ECM) structure secreted by the membrane of the sheath cell (also known as the theocogen) using fine connectors (Thurm, U. and Küppers, J., 1980).

As well as the sheath cell and the ciliated sensory neuron itself, two other cell types form the mechanosensory apparatus. The trichogen (shaft) cell forms the hair, which is most obvious in the bristle organ. The tormogen (socket) cell forms the joint membrane at the base of the hair. Both cells retract from the cuticle later in development to form the outer sensillum lymph cavity. This cavity is isolated from the rest of the subcuticular cavity by a seal formed by the periphery of the tormogen cell.

The sensillum lymph is high in K^+ and low in Na^+ ions (Thurm, U. and Küppers, J. 1980; Grünert, U. and Gnatzy, W., 1987). The supporting cells, actively transporting potassium ions from the hemolymph, maintain this ionic balance. By analogy with vertebrate hair cells, it is probable that the movement of the cilium causes an opening of cation channels allowing a rapid flood of K^+ into the neuron and leading to neuronal depolarization. As we have already discussed in relation to the cnidarian nematocyst, many mechanoreceptors show a directional sensitivity; movement of the cilium in the opposite direction inhibits receptor potential. Insect mechanoreceptors, at least those found on the bristle organ, also show the same profile (Corfas, G. and Dudai, Y., 1990). While many mechanoreceptors can be incredibly sensitive, the response decreases if deflection is sustained, that is, the cells show adaptation (Walker, R. G. *et al.*, 2000).

Models have been proposed that draw similarities to the gating-spring model proposed for vertebrate hair cell function (Gillespie, P. G. and Walker, R. G., 2001). This model requires that an ion channel be anchored under tension between the ciliary cytoskeleton and the dendritic cap. Deflection causes a certain number of channels to open; further deflection would cause more channels to open. Indeed adaptation is proposed to use a similar mechanism to the vertebrate hair cell, where the channel on the cilium would slide along the cytoskeletal tracks, in one direction passively and in the other direction using a molecular motor, thereby altering the tension on the channel.

The relevant structural features of insect mechanoreceptors can be clearly seen in the bristle mechanoreceptors. Here the dendritic cap links the cilium of the sensory neuron to the hair embedded in the cuticle of the insect. Another mechanoreceptor, the campaniform sensillum, is quite similar to the bristle organ and is responsive to deformation of the cuticle. Rather than connecting to a hair, the ciliated dendrite makes a connection with a button on the cuticle, the dome cuticle. The organization of this structure closely mirrors that of the bristle organ with perhaps some alteration in the function of the trichogen cell.

The structure of the chordotonal (also known as the scolopidial) cell is, at first sight, somewhat divergent; however, it still follows the organule plan of insect mechanoreceptors, even though the morphology and arrangement of the cells are somewhat different. The chordotonal organ is used as an internal pressure sensor; however, it is also the mechanoreceptor responsible for hearing in many insects. In contrast to the rather solitary bristles and sensilla, the chordotonal units (known as scolopidia) are organized into arrays in the various regions of the insect. The structure of a typical insect bristle mechanoreceptor is illustrated in Figure 10.

The main feature of the scolopidium is the scolapale space, a fluid-filled, spindle-shaped space (Todi, S. V. *et al.*, 2004; Yack, J. E., 2004). This space encloses the ciliated dendrite of the type I sensory neuron, the cilium of which is suspended between two surfaces where it responds to vertical deflections and deformation. The cilium itself is encased in the dendritic cap (more correctly called a dendritic sheath) made by the theocogen (sheath) cell. Just before entering the sheath, the cilia show a dilation containing an

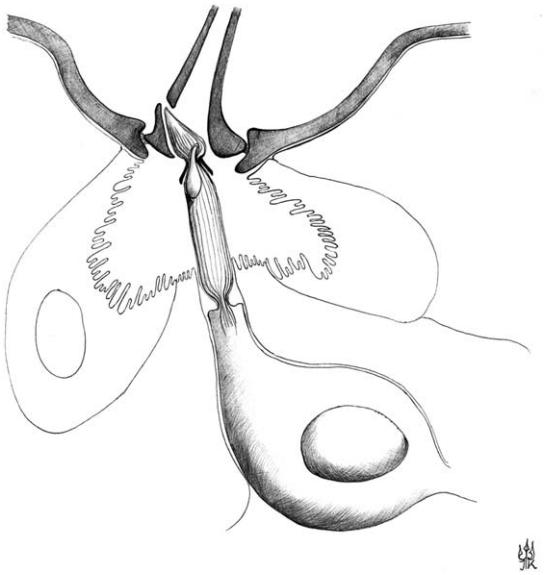

Figure 10 A schematic drawing of the structure of a typical superficial insect mechanoreceptor, in this case a bristle organ. The cytological plan of chordotonal organs is similar to that shown here. Mechanosensation is thought to depend on the relationship between the cilium and its dendritic cap. An original drawing by Johanna Kraus, all rights reserved.

electron-dense oval body. The cilium itself shows the same axoneme pattern, 9 peripheral doublets of microtubules without any central filaments ($9 \times 2 + 0$). Proximally there are extensive ciliary rootlets that run far into the cell body of the neuron, indeed some pass the nucleus. Scolopidia that are responsible for hearing are typically innervated by two or, sometimes, three type I ciliated sensory neurons (Hallberg, E. and Hansson, B. S., 1999). The significance of this is unclear. There is yet more variation at the distal end of the scolopidium; in one type of scolopidium, known as amphinematic, the cilium is attached to the distal cuticle through the elongated dendritic sheath connected to what can be considered to be a modified tubular body of the cilium. The other type of scolopidium is the mononematic. Here, the cilium is indirectly connected to the distal integument through a cuticular cap (provided by the dendritic sheath) that is in turn associated with one or two distally located attachment cells (Yack, J. E., 2004). In both types of scolopidium are massive bundles of actin cables, the scolopale rod, that give the scolopale cell (which can be considered to be a modified theocogen or sheath cell) its stiffness and afford some tension on the ciliated dendrite. These rods have also been used to suggest a mechanism of mechanotransduction based on a string on a bow model (Todi, S. V. *et al.*, 2004; 2005).

As mentioned earlier, the scolopidia are used in some insects as auditory mechanotransducers. The array of scolopidia that constitute the hearing organ is called, in flies, Johnston's organ (Boekhoff-Falk, G., 2005). In the fruit fly *Drosophila* and in the mosquito, this is found as a specialized region in the joints between basal segments of the antennae. However, this is not the case in all insects. In the bladder grasshopper, the main hearing organ is found in the first abdominal segment, with five smaller organs on abdominal segments A2–A6, and in the hawkmoth the hearing organ is found located just lateral to the tongue (van Staaden, M. J. and Römer, H., 1998; Göpfert, M. C. and Wasserthal, L. T., 1999). An interesting aside here, and one outside the scope of this chapter, is the further diversity of hearing organs within insects. In many insects, where sound plays a very important role in their lives (e.g., for mating, prey detection, and predator avoidance), as in some moths and true crickets, the animal uses a tympanal hearing organ (Stumpner, A. and von Helversen, D. 2001; Yack, J. E., 2004). This is characterized externally by a cuticular-derived tympanal membrane, which is deflected by sound. The tympanum is associated internally with an air sac derived from a trachea. The scolopidia are attached to the air sac or to the tympanal membrane.

Drosophila is used as the major insect model organism and the ability to identify molecules by directed genetic screens makes this preeminent in defining the components of the transduction system involved in mechanosensation. Two such screens have been carried out. Kernan M. *et al.* (1994) took extracellular recordings of bristle organs of mutagenized larvae, finding a number of genes through which mechanosensation was affected. Eberl D. F. *et al.* (1997) used a property of *Drosophila* courtship behavior for their screen. Male *Drosophila* will vigorously court when they hear a component of the mating sound (known as the pulse sound) produced when the wings are rubbed together (Bennet-Clark, H. C. and Ewing, A. W., 1970). In fact this sound is so effective that when presented with a recording of it, male *Drosophila* will court other males (von Schilcher, F., 1976). This provided a very simple behavioral screen.

In total, Eberl D. F. *et al.* (1997) identified 15 mutants in which auditory mechanosensation was perturbed. Many of these genes have now been identified. Possibly the most intriguing discovery, and one that indirectly led to the identification of a vertebrate mechanotransducing channel, is the identification of the *No mechanoreceptor potential C* gene or *NompC* (Walker, R. G. *et al.*, 2000). Flies that are mutant for *NompC* show a complete absence of mechanoreceptor potential in bristle organs. The product of the *NompC* gene is a part of the TRP (transient receptor potential) gene family. This provoked a great deal of interest, as the TRP family had been shown to mediate a large number of sensory processes such as vision, chemosensation, thermosensation, and osmosensation (Montell, C., 2005). Furthermore, this family was represented in numerous species from different phyla, ranging from nematodes (*C. elegans*) to vertebrates. The vertebrate homolog of NompC is in the TrpN subgroup and seems to form part of the mechanotransduction complex in fish (Sidi, S. *et al.*, 2003). However, the only vertebrates where a *TrpN*/*NompC* has been found are fish and frogs; *TrpN*/*NompC* has not been found in birds or mammals and indeed it appears to have been deleted in the mammalian and chicken genome (Boekhoff-Falk, G., 2005; Gillespie, P. G. *et al.*, 2005). *TrpN1* is expressed at the tip of the microtubule-based kinocilium of the frog hair cells (Shin, J. B. *et al.*, 2005), whereas TrpA1 is found at the tip of the actin-based stereovilli (Corey, D. P. *et al.*, 2004). As we

have already described, mammal and, to a significant extent, avian hair cells do not have a kinocilium, relying instead on just the stereovilli. Indeed it is possible to correlate the presence of TrpA1 and TrpN1/NompC with the presence of stereovilli and kinocilia in the ciliated mechanoreceptors. Unex-pectedly, the absence of an inner ear phenotype of *TrpA1* mutants (despite an absence of auditory response in other forms of ablation in the mouse) suggests that there may be another, as yet uncharacterized participant in the mechanoreceptor transduction channel of vertebrate hair cells (Kwan, K. Y. *et al.*, 2006).

A cautionary note: while *NompC* mutants show no mechanoreceptor potential in the bristle organs, auditory function is more or less normal. This indicates that other Trp channels operate in Johnston's organ, the auditory organs of the fly. Indeed two *TrpV* homologs can be detected, and both are localized to the proximal part of the ciliated dendrite (Kim, J. *et al.*, 2003; Gong, Z. *et al.*, 2004). Interestingly, the localization of TrpV channels is mediated by heterotetramerization with another unknown channel that is more localized. Mutants for either *Drosophila TrpV* channel show mislocalization of the other channel to the ciliated dendrite (Gong, Z. *et al.*, 2004). Thus far, *TrpV* homologs in vertebrates have not been characterized.

Other molecules that are important in vertebrate mechanoreception have also been shown to play a role in *Drosophila* mechanosensation. Mutations, in mammals, of the atypical myosin VIIa result in stereovilli that are incorrectly positioned and disarrayed, and indeed this is the cause of the human deafness syndrome Usher 1B (Hasson, T. *et al.*, 1995; Weil, D. *et al.*, 1995). In flies that are mutant for the myosin VIIa homolog *crinkled*, the scolopale cells are disorganized, perhaps due to a loss of the apical attachment of this cell (Todi, S. V. *et al.*, 2005).

Another molecule that appears in both mammalian and *Drosophila* hearing organs is prestin, a member of the solute carrier-26 (SLC26) family (Weber, T. *et al.*, 2003). The SLC26 family has diverse functions; in particular they are anion exchangers. In mammals, prestin is found in outer hair cells of the cochlea; however, it does not act as an anion transporter. Instead it acts as a motor driving cochlear amplification of sound signals (Zheng, J. *et al.*, 2000). Cochlear amplification via prestin (as contrasted with cochlear amplification by an active bundle mechanism; Manley, G. A., 2001) is a process that occurs exclusively in mammals (Géléoc, G. S. and Holt, J. R., 2003). Its presence in the auditory structure of the fly is therefore perhaps unexpected and until the function of *Drosophila* prestin is elucidated, statements about the relationship between the fly and vertebrate prestin homologs will be speculative.

This brings us to consider the larger issue of homology between the insect scolopidium and the vertebrate inner ear hair cell. Morphologically, the difference is simple; flies uses the deflection and deformation of a ciliated dendrite made of microtubules for mechanosensation, while vertebrates use actin-based stereovilli. Despite the presence of homologous molecules, mechanistically there must be differences between both modes of mechanosensation.

3.01.4.4 Mollusk Hair Cells

Thus far we have discussed nonchordate mechanoreceptors in cnidarians, a basal metazoan, and in nematodes and insects, both examples of Ecdysozoa (moulting animals). This leaves the lophotrochozoans. Ecdysozoa and Lophotrochozoa are protostomes; however, the two lineages diverged soon after the protostomes/deuterostomes split. Thus, an evolutionary perspective needs an example from the Lophotrochozoa. Mollusks are the largest group in this taxon and are also the most diverse. They range from chitons (Polyplacophora), snails and slugs (Gastropoda), bivalved animals such as oysters (Bivalvia) to octopuses, squids, and *Nautilus* (Cephalopoda). We will focus on the ciliated mechanoreceptors of cephalopods, which are perhaps the most advanced of invertebrate mechanoreceptors.

Cephalopods have a very well developed nervous system, and indeed remarkable sensory organs that are comparable in complexity to those found in vertebrates. It is the statocyst that attracts our attention. This organ helps maintain equilibrium, sensing linear (gravitational) and rotational acceleration (Budelmann, B. U. *et al.*, 1997). The statocyst is essentially a closed cavity that is lined with a complicated arrangement of specialized epithelia dotted with ciliated mechanoreceptors. Statocysts of simpler cephalopods (*Nautilus*) are completely lined with sensory epithelia and half-filled with a number of calciferous granular statoconia and with endolymph (Neumeister, H. and Budelmann, B. U., 1997). There are two types of mechanoreceptor in the *Nautilus* statocyst; type A is found in the ventral half, the hemisphere of the statocyst where the statoconia are found. type B mechanoreceptors are found in the dorsal hemisphere, in the region containing the endolymph.

The mechanoreceptors found in *Nautilus* are primary sensory neurons, that is, an axon leaves the basal part of the cell, joining with a complicated nerve plexus underneath the statocyst epithelium. A type A mechanoreceptor cell typically carries between 10 and 15 kinocilia, arranged in a single row, which is inclined toward the cell surface. The kinocilia are of the typical $9 \times 2 + 2$ configuration. The microtubules connect to the basal body, which in turn is part of an extensive basal root network. Running parallel to the kinociliary row and right beside each kinocilium is a row of shorter microvilli (Neumeister, H. and Budelmann, B. U., 1997). The rows of kinocilium and microvilli are not centered on the cells, but are polarized, displaced to the periphery on the cell. Not only the bundles but also the basal root network is polarized and points in the same direction as the kinocilium. Two interesting points are that the long axis of the kinociliary row is horizontal to the equator of the statocyst and that the polarization of each type A cell (that is to say the side of the cell to which the row is located) is the same for neighboring cells, suggesting a more global mechanism for polarizing type A mechanoreceptors in *Nautilus*. The association of these cells with the statoconia suggests a role in the sensation of gravity and other forms of linear acceleration.

A type B mechanoreceptor cell has 8–10 kinocilia, and as in the type A, these are placed on one side of the cell. Unlike the type A cells, however, the kinocilia are not arranged in a row but have an almost haphazard arrangement, although it is reported that some seem to have a circular configuration. There are again shorter microvilli on these cells, but they are more numerous than those found in the type A mechanoreceptors. These mechanoreceptors, and their association with the endolymph, are thought to be responsible for sensing angular acceleration (Neumeister, H. and Budelmann, B. U., 1997).

The statocysts of Coleoid cephalopods are more complicated than those of *Nautilus* (and in turn other mollusks). There are two main types, the Octopoda type and a Decapoda type which share some features. Contained in the statocyst is the gravity-sensing organs containing a macula/statolith system that is quite separate from the angular acceleration sensing organ that consists of a crista/cupula system. In the Octopoda type, the crista/cupula system is subdivided into nine segments, arranged so they can detect movements in the three spatial dimensions. The Decapoda type is irregularly shaped, as cartilaginous lobes protruding into the cyst direct the flow of the endolymph. It has three maculae, with a statolith attached to one and statoconia to the other two, arranged at right angles to each other. The crista/cupula system of the Decapoda is subdivided into four segments, arranged into three dimensions.

The mechanosensory cells found in these statocysts resemble the type A mechanoreceptors; however, while *Nautilus* has between 10 and 15 kinocilia per cell, the Octopoda- and Decapoda-type mechanoreceptors have between 50 and 150 kinocilia per cell (Figure 11). Cells similar to the type B mechanoreceptors in *Nautilus* are not found in these cephalopods (Budelmann, B. U. *et al.*, 1973). Again all

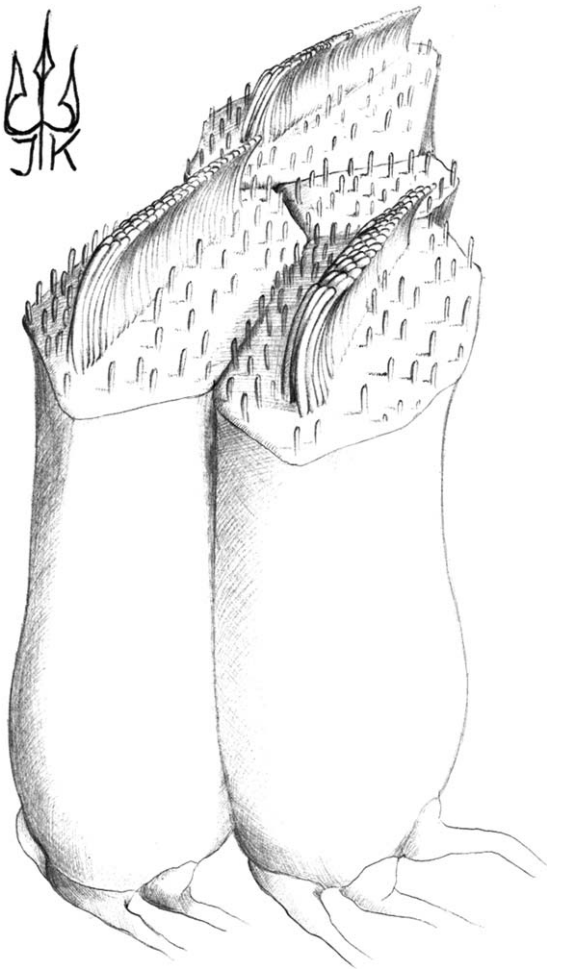

Figure 11 A schematic drawing of a cephalopod hair cell carrying a large number of kinocilia that are flanked by very much smaller microvilli. The ciliary bundles are displaced to one side of the cell, and the cilia themselves are angled toward the surface of the cell. An original drawing by Johanna Kraus, all rights reserved.

kinocilia are of the same length, arranged in a row along the long axis of the cell. All are inclined toward the surface of the cell, showing the same kind of polarization as found in *Nautilus*. The kinocilia are also associated with microvilli, found in parallel rows either side and next to the kinociliary row. These are not stereovilli as found in vertebrates, and there seem to be no tip links associating the microvilli to the kinocilia. Instead, each kinocilium is associated with the other by membrane junctions (Budelmann, B. U. *et al.*, 1973). The significance of this is still unclear.

At this point it is worth mentioning that other mollusks, that is, most gastropods and bivalves, have mechanoreceptors that are similar to the *Nautilus* type B mechanoreceptor (a random or circular arrangement of kinocilia); however, they are unpolarized. As such, the lack of polarization suggests that they are involved only in gravity sensation (McKee, A. E. and Wiederhold, M. L., 1974; Moir, A. J., 1977). Polarization of the basal feet with respect to the kinocilium is thought to correlate with the deflection of the kinocilia. Deflection in the direction of the basal feet causes maximum depolarization while deflection away from the basal foot causes hyperpolarization (Budelmann, B. U. and Williamson, R., 1994). This is important for detecting the directions of linear and angular acceleration.

One important difference between coelid cephalopods and other mollusks is that the mechanoreceptors found in the statocyst are predominantly secondary sensory cells (Stephens, P. R. and Young, J. Z., 1982; Budelmann, B. U. *et al.*, 1987). One exception is in the crista, which is a ridge of cells. In the middle of the ridge are 2 or 4 rows of larger hair cells and 2–4 less regularly arranged hair cells on either side. In the octopuses (the coelids that have been studied) the hair cells on one side of the ridge are primary, while on the other side, they are secondary. These secondary cells are large or small and are synaptically connected to two types of afferent neurons. No other animal has both primary and secondary sensory cells in the same epithelium.

The ionic character of the cephalopod hair cell is almost identical to that of vertebrates. This may indicate that a similar mechanoreceptor channel system acts, but as yet the molecular correlates for mechanosensation in mollusks are unknown. We would expect a Trp receptor to form a part of a presumptive spring-gated channel, similar to that found in vertebrates.

3.01.5 Molecular Evolution of Mechanoreceptors

In the preceding sections we described cellular relatedness between vertebrate and nonvertebrate ciliated mechanoreceptors and we find that these cells share certain characteristics that make them able to respond to mechanical stimuli. However, one important question remains: are ciliated mechanoreceptors in different species monophyletic or the result of convergent evolution? To fully answer this, the developmental program, or ontogeny, of mechanoreceptors from different species needs to be examined. In this section, the agents that transmit this information, the genes, are discussed. Only by understanding the molecular core of mechanoreceptor development can we be informed regarding a monophyletic or polyphyletic origin.

In a typical developmental/differentiation paradigm, an external signal – emitted, for example, by an adjacent group of cells – elicits a response in a target cell, a process known as induction. Induction usually results in the activation of a protein that acts on DNA. Such proteins, called transcription factors, bind stretches of DNA, known as *cis*-regulatory elements, and activate the genes controlled by these regions. These genes form a hierarchical organization of fate choices in the form of a transcription factor cascade. This becomes important when the consensus view of molecular evolution is taken into consideration. At the molecular level, developmental programs evolved as conserved genetic regulatory pathway are subtly modified, usually at the level of *cis*-regulatory elements and by equally subtle changes in the activity of a particular protein. Thus to extend the presumed cytological homology to the molecular level, an appreciation of the conservation of gene networks, in particular transcription factor cascades, is important. At this point we introduce an important caveat; developmental biology uses a limited number of model systems, comparative biology (by definition) needs far more. More specifically, much is known about the molecular networks that control the development of mechanoreceptors in vertebrates and in *Drosophila*; however, much less is known about the genetic cascades involved in the development of the other species considered. Therefore, any discussion about molecular comparisons makes large assumptions in the light of a somewhat limited data set. Notwithstanding, by identifying homologous genes from the phyla discussed, it is possible to be

informed on the validity of these assumptions, and indeed many genes involved in the development of vertebrate or fly mechanoreceptors can be found in cnidarians, nematodes, and cephalopods.

3.01.5.1 Development of Ciliated Mechanoreceptors

Ciliated mechanoreceptors are almost exclusively restricted to the ectodermal lineage of all animals. This highlights that the development of the mechanoreceptors is constrained by the molecular history of the cell. Indeed, mechanoreceptor cytodifferentiation can be thought of as the end product of a gradual restriction in cell fate, with each step being represented by a progression in the genetic transcription factor cascade.

In vertebrates, the ciliated mechanoreceptors form from a specialized, thickened region of epithelium, the sensory placode (Baker, C. V. and Bronner-Fraser, M., 2001). For the purpose of this review we discuss the vertebrate inner ear that forms from the otic placode. The otic placode is specified from ectoderm already committed to adopt a sensory fate. This pre-placodal domain is specified by surrounding tissues and refers to a territory of the vertebrate embryo that will give rise to not only the otic placode, but also other sense organs, peripheral neurons of the head and the lens. The pre-placodal domain is marked by families of transcription factors showing homology to a number of genes originally cloned in *Drosophila*: *distalless* (*dlx*) gene, the *sine oculis* (*six*) gene, and *eyeless* (*eya*) family (Schlosser, G., 2005). In flies these genes also play a role in epithelial patterning and outgrowth; however, it is not clear whether the role of these genes in the fly is to establish a field of competence or whether they participate more directly in the genetic cascade that leads directly to the formation of the mechanoreceptor.

3.01.5.1.1 Extrinsic factors regulating mechanoreceptor development

The early development of mechanoreceptors depends on the action of extrinsic factors. These act on competent ectoderm and are usually signaling molecules acting on cells to direct them to adopt a ciliated mechanoreceptor fate. The extrinsic mechanisms are not very well conserved between different phyla, and indeed there is considerable variability even within vertebrates. Thus their individual descriptions are not so pertinent to this discussion and will not be dealt with in depth. In vertebrates, a specific area of the pre-placodal region is acted upon by localized signaling interactions that direct the formation of the otic placode within this territory (Groves, A. K. and Bronner-Fraser, M., 2000; Ladher, R. K. *et al.*, 2000; Kil, S. H. *et al.*, 2005). This early phase of signaling is mediated, in vertebrates, by members of the fibroblast growth factor (FGF) family in combination with the wingless (WNT) family and induces pre-placodal ectoderm to adopt an otic fate (Schlosser, G., 2006). In *Drosophila*, the role of this early signaling in the development of the mechanoreceptors is not clear; Niwa N. *et al.* (2004) suggest the existence of a pre-proneural state that depends on the action of *decapentaplegic* (the fly homolog of *Bmp2/4*) and *wingless* (*wnt*).

The induced vertebrate inner ear invaginates to form an otocyst within the mesenchyme of the head. During this process extrinsic signals once again specify different territories within the inner ear. The otocyst is embedded in head mesoderm and flanked by the neural tube and endoderm, tissues that to varying extents exert some influence onto the otocyst (Wu, D. K. and Oh, S. H., 1996; Wu, D. K. *et al.*, 1998; Riccomagno, M. M. *et al.*, 2002; Bok, J. *et al.*, 2005; Riccomagno, M. M. *et al.*, 2005). In amniotes, where the studies have been performed, the hindbrain and the notochord provide the otocyst with dorsal and ventral identities, respectively. Recent reports described the antagonistic effect of Wnt3a, emanating from the hindbrain, and sonic hedgehog, from the notochord, directing development of the vestibular and auditory portions of the otocyst (Riccomagno, M. M. *et al.*, 2002; 2005). As has already been described, the morphology of hair cells is different in the two parts of the inner ear, leading to the speculation that the action of these extrinsic factors has a direct bearing on the differentiation of the hair cell subtypes. Finally, there is a role for extrinsic signals in the differentiation of the hair cells of the cochlea. Montcouquiol M. and Kelley M. W. (2004) showed that without mesenchyme, pattern and differentiation within the cochlea are perturbed.

Hair cells form from regions of the otocyst known as sensory patches. The sensory patches express a number of extrinsic factors that have been shown to play a role in mechanoreceptor development. In vertebrates, the sensory patches are specified by Notch and its ligands and by BMP molecules; however, both groups of molecules have additional functions later in development. As already mentioned, in flies, sensory

patches are though to be specified by the combined action of *decapentaplegic* and *wingless* (Niwa, N. *et al.*, 2004). Subsequent differentiation is triggered by the *Notch* ligand *Delta* (Schweisguth, F., 1995). It should be noted that in both vertebrates and insects, the mechanisms that specify exact mechanoreceptor identity do so in parallel to the differentiation of the sensory patches.

In vertebrates, *Bmp7* is expressed very early in the inner ear (Oh, S. H. *et al.*, 1996), with its close family member *Bmp4* appearing soon after. In chickens, *Bmp4* is expressed in all the sensory patches, and in mouse and zebrafish it is expressed in most (Oh, S. H. *et al.*, 1996; Morsli, H. *et al.*, 1998; Mowbray, C. *et al.*, 2001). While the overexpression of BMP7 has not been studied, BMP4 has been investigated. These data support a role for BMP4 as a permissive factor, allowing the differentiation of the inner ear hair cells; ectopic application of BMP4 increases the number of hair cells that are found, and application of a BMP4 antagonist decreases their number (Chang, W. *et al.*, 1999; Gerlach, L. M. *et al.*, 2000; Gerlach-Bank, L. M. *et al.*, 2004; Li, H. *et al.*, 2005). However in all cases, the experiments were performed too late to address any role in the formation of the sensory patches themselves. Furthermore, these experiments have only been performed in the chicken; and while BMP molecules are expressed in the inner ear, and more pertinently for us in the sensory patches, their function has not been addressed in other vertebrates.

The notch family of signaling molecules comprises the *Notch* receptors and its ligands, *Delta* and *Jagged/Serrate*. Signaling between these molecules occurs between neighboring cells and in the plane of the cell. More detail on the signaling pathway is provided in several excellent reviews (Fekete, D. M. and Wu, D. K., 2002). Notch–DSL (for Delta, Serrate, and Lag-2, the *C. elegans* homolog of Delta) signaling plays two roles in the development of ciliated mechanosensors; the first is in the specification of the sensory patches, imparting competence onto particular regions of the otocyst so that they can adopt a sensory fate. This property is mediated by the interaction of Notch with Jagged1 (also known as Serrate); Notch overexpression results in the production of supernumerary sensory patches, while knockouts of the *Jagged1* gene result in the loss of hair cells (Daudet, N. and Lewis, J., 2005; Brooker, R. *et al.*, 2006). The second role is within the sensory patch itself. It appears that Notch signaling is important in the fate choice between hair cells and the associated accessory cells, the supporting cells. The role of Notch in the binary fate choice between hair cells and supporting cells was demonstrated by work in fish, chicken, and mouse. Loss- and gain-of-function analysis using Notch, its ligands, or its downstream effectors has shown that sensory cells expressing one of the Notch ligands cause the activation of Notch in adjacent cells. Hair cell fate is inhibited in these adjacent cells which then become supporting cells. In contrast to sensory patch specification, this effect, termed lateral inhibition, is mediated by the interaction of Notch with Delta (Brooker, R. *et al.*, 2006).

Drosophila mechanoreceptors develop from patches of epidermis known as sensory organ precursors (SOPs). The development of the SOPs themselves is subject to patterning cues acting on the epidermis: *dpp* (the homolog of *Bmp/2/4*) and *wingless* act in concert to specify the SOP, together with ecdysone, the hormone that regulates the timing of metamorphosis of the *Drosophila* larva (Niwa, N. *et al.*, 2004). In addition, epidermal growth factor (EGF) signaling specifies some of this group of cells (Okabe, M. and Okano, H., 1997). This has parallels with the development of vertebrate hair cells: EGF is required for the survival and proliferation of mouse hair cells (Doetzlhofer, A. *et al.*, 2004). The concerted action of *dpp*, *wingless*, and EGF causes a group of cells within the *Drosophila* ectoderm to become specified as proneural. Lateral inhibition mediated by an interaction between Notch and Delta then specifies one of the proneural cells as the sensory precursor cell (Schweisguth, F., 1995).

3.01.5.1.2 The role of transcription factors in mechanoreceptor development

The action of extrinsic factors, that is, signaling molecules not acting cell-autonomously, has been described in the preceding section. These must provoke an intracellular response that affects the changes wrought on the cell by extracellular events. The intracellular response is invariably mediated by transcription factors that bind to specific DNA sequences, activating particular genes that lead to a particular developmental outcome. The transcription factor cascade involved in mechanoreceptor development is dynamic and the same transcription factors recur within different contexts and with slightly different functions as the mechanoreceptor becomes more and more differentiated.

Near the top of the hierarchy of transcription factors regulating mechanoreceptor development is the paired-box homeodomain-containing protein

Pax2. In vertebrates, *Pax2* is one of the first genes expressed in the inner ear primordia. In most phyla, the expression of *Pax2*, or its ancestral ortholog *Pax2/5/8*, prefigures the development of ciliated mechanoreceptors. The *Pax2/5/8* ancestor *PaxB* can be found in cnidarians (Sun, H. *et al*., 1997; Gröger, H. *et al*., 2000; Miller, D. J. *et al*., 2000). Expression analysis in hydrozoa localized *PaxB* to the developing sensory neurons of the tentacles (Gröger, H. *et al*., 2000) while in cubozoans, *PaxB* can be found in the statocyst (Kozmik, Z. *et al*., 2003). In *Drosophila*, the *Pax2* homolog is found in mechanoreceptors, and mutation results in a loss of the bristle organs; other mechanoreceptor subtypes were not investigated (Czerny, T. *et al*., 1997; Kavaler, J. *et al*., 1999). Mollusk *Pax2/5/8* has also been described and is expressed in both the chemosensory and mechanosensory cells (O'Brien, E. K., and Degnan, B. M., 2003). Finally, either *Pax2* itself or the *Pax2/5/8* gene can be found in deuterostome lineages, for example, in echinoderms (Czerny, T. *et al*., 1997), cephalochordates (Kozmik, Z. *et al*., 1999), and vertebrates (Krauss, S. *et al*., 1991; Rinkwitz-Brandt, S. *et al*., 1996; Torres, M. *et al*., 1996; Heller, N. and Brandli, A. W., 1997; Hutson, M. R. *et al*., 1999; Hidalgo-Sanchez, M. *et al*., 2000; McCauley, D. W. and Bronner-Fraser, M., 2002). It is tempting to suppose that the *Pax2* gene plays a fundamental role in establishing a mechanosensory propensity; however, as with all generalizations, caution must be applied.

In vertebrates, *Pax2* operates upstream of *Notch* to specify an area of ectoderm competent to become mechanosensory (Groves, A. K. and Bonner-Fraser, M., 2000). These cells then, through subsequent interactions, become definitively mechanosensory. In *Drosophila*, however, the role of *Pax2* is downstream of *Notch* and specifies the mechanosensory lineage (Kavaler, J. *et al*., 1999). However, this may reflect a difference between vertebrates and *Drosophila*; vertebrates use a placodal sense organ, arranging the ciliated mechanosensory receptors in specialized structures, whereas in *Drosophila* this is not the case. Analysis of *Pax2* mutants in the mouse and zebrafish indicate that the initial development of the inner ear is normal, due to a degree of redundancy with the *Pax8* gene, a close relative of *Pax2* (Hans, S. *et al*., 2004). In mice mutant for *Pax2*, however, the auditory portion of the inner ear fails to form (Favor, J. *et al*., 1996; Torres, M. *et al*., 1996). The formation of mechanoreceptors is apparently normal in the rest of the ear, as there are still cells positive for markers of early mechanoreceptors (Burton, Q. *et al*., 2004). Zebrafish have two *Pax2* genes, and mutations in one of them actually results in an increased number of hair cells by disrupting the expression of *Delta* (Riley, B. B. *et al*., 1999). Both sets of data do not emphatically rule out a role for *Pax2* in the direct specification of ciliated mechanoreceptors; the mouse study relied on molecular markers for assaying hair cells, without observing the final morphology of the hair cells. One cannot rule out the possibility that the hair cells had merely arrested at an earlier, *Pax2*-independent step of their development. In the zebrafish study, only one of the two *Pax2* genes was mutated. When both *Pax2a* and *Pax2b* are mutated, hair cell number is reduced (Whitfield, T. T. *et al*., 2002). These data are similar to those from *Drosophila*; when *Pax2* is lost, the external sensory organs of the fly are lost (Kavaler, J. *et al*., 1999).

Another transcription factor that plays an important role in the specification of the ciliated mechanoreceptors is the transcription factor *Atoh1*. *Atoh1* is one of the four vertebrate orthologs of the *Drosophila* gene *atonal*. Genetic ablation of *Atoh1* (formerly known as *Math1*) blocks the formation of the hair cells without any impact on other cell types (such as supporting cells) or on the overall morphology of the inner ear (Bermingham, N. A. *et al*., 1999). Mutation of the *Drosophila atonal* indicates its requirement for differentiation of the scolopidia in the fly; mutants of *atonal* completely lack these cells as well as some other sensory cell types. The functional similarity between the fly *atonal* and vertebrate *Atoh1* (*Atoh1* can rescue a fly *atonal* mutant and vice versa; Ben-Arie, N. *et al*., 2000; Wang, V. Y. *et al*., 2002) lends support to a homology between fly and vertebrate ciliated mechanoreceptors. However, closer inspection reveals important functional differences between *Drosophila* and vertebrates. These differences, reviewed by Hassan B. A. and Bellen H. J. (2000), highlight important mechanistic changes between the fly and vertebrates. In the fly, *atonal* functions in cell selection within the SOP and mediates the elaboration of chordotonal lineage identity, that is, proneural and lineage identities are coupled. In mouse, *Atoh1* functions in postmitotic cells, directing only terminal differentiation of the hair cell (Chen, P. *et al*., 2002). Indeed while *Atoh1* mutant mice do not have hair cells, the prosensory domain (the sensory patches) are unaffected. In vertebrates, the proneural and lineage identity function of *Atoh1* has become uncoupled. This is not because of a structural change in the molecule itself; *Atoh1* will rescue flies mutant for *atonal*, and *atonal* completely

rescues the *Atoh1* knockout mouse (Ben-Arie, N. *et al.*, 2000; Wang, V. Y. *et al.*, 2002). Furthermore, transfection of *Atoh1* into mammalian postnatal inner ears results in the formation of extra hair cells (Kawamoto, K. *et al.*, 2003; Woods, C. *et al.*, 2004). Seemingly *Atoh1* is both necessary and sufficient for the development of the vertebrate ciliate mechanoreceptor.

Atoh1 regulation is still unclear and thus is subject to some speculation. An ablation of the *Sox2* gene in the otocyst has been shown to also abolish the development of the hair cells (Kiernan, A. E. *et al.*, 2005). *Sox2* affects the development of the sensory patches rather than the differentiation of the hair cells themselves and epistatic studies have shown that *Sox2* functions upstream of *Atoh1* (Kiernan, A. E. *et al.*, 2005). *Atoh1* is also under negative regulation from the downstream effectors of notch–DSL signaling, the *HES* genes, genes that are the vertebrate orthologs of the *Drosophila enhancer of split* genes (Zine, A. *et al.*, 2001). Again this is not so surprising given the effect Notch has on the determination of the hair cells.

In *Drosophila*, *atonal* expression is regulated by a cascade of transcription factors. It is regulated by a zinc-finger protein called senseless and there are contributions from genes such as *pannier* and *u-shaped* as well as *distalless* and *homothorax* (Quan, X. J. *et al.*, 2004). While the vertebrate homolog of *senseless*, *Gfi1*, is involved in hair cell function, its relationship with *Atoh1* is not clear (Jafar-Nejad, H. and Bellen, H. J., 2004). *Gfi1* has itself been mutated in mice and these animals also show hair cell abnormalities (Wallis, D. *et al.*, 2003). In the inner ear, *Gfi1* has been identified as a downstream response of the transcription factor, *Pou4f3*, the causative mutation of the autosomal human hereditary deafness gene DFNA15. The relationship with *Atoh1* has not been elucidated, however, and it is still unclear whether *Atoh1* functions upstream, downstream, or in parallel with *Pou4f3*. Hertzano R. *et al.* (2004) showed that in mice mutant for *Pou4f3*, *Atoh1* expression was at 50% of its normal levels. *Gfi1* functions downstream of *Atoh1* in the development of secretory cells in the mouse intestine, suggesting that there may also be a similar relationship within the inner ear (Shroyer, N. F. *et al.*, 2005). Of the other genes suggested to play a role in the regulation of *Drosophila atonal*, homologs for *pannier* (*GATA*), *u-shaped* (*FOG*), *distalless* (*dlx*), and *homothorax* (*Meis*) can all be found in vertebrates and the expression can be detected in the inner ear. However, the detailed molecular relationships of these genes with each other and with *atonal*/*Atoh1*, either in the fly or in vertebrates, are still to be elucidated.

3.01.5.2 Summary of Development

Focusing on mechanoreceptor development in flies and in vertebrates allows important genes to be defined. Orthologs for these genes can also be found in all of the organisms we described. As discussed, *Pax2* orthologs can be found in every metazoan phylum including Porifera, the sponges (Hadrys, T. *et al.*, 2005). *Atonal*, involved in the development of mechanoreceptors in both vertebrates and insects, is also found in cnidarians, nematodes, and mollusks (Ladher, R., Tarui, H., and Agata, K. unpublished data). *Notch* and *Delta*, involved in fate choice within the sensory precursors in the fly and in the development of the sensory patches in vertebrates, can also be found in cnidarians, nematodes, and mollusks (Ladher, R., Tarui, H., and Agata, K. unpublished data). The list goes on, with genes involved in mechanoreceptor development in vertebrates being found as far back as cnidarians. This suggests a conservation of the molecular modules that could direct development of the ciliated mechanoreceptors. The could is important though, as in other organisms the involvement of these genes in mechanoreceptor development can only be postulated but has not yet been unequivocally shown. Indeed Fritzsch B. *et al.* (2006) have suggested that the presence of homologous genes suggests a deep homology describing a basic cellular property (such as the ability to rapidly proliferate), not really describing a derived structure, and that any attempt to describe further homologies is likely to fail. In fact many homologous genes are not exclusively mechanosensory but are found in other contexts during ontogeny.

Further resolution of the homology question will require more data, particularly from nonmodel species. At this stage, there is no doubt that ciliated mechanoreceptors share important molecular, structural, and cytological similarities. However, as well as these obvious similarities, ontogenetic differences become very important to characterize, enabling us to understand where and how the ciliated mechanoreceptor has arisen and how evolution has modified the ancestral prototype in the different lineages.

3.01.6 Conclusion

There is a considerable amount of information on the structure, function, and development of ciliated mechanosensory cells in vertebrates and invertebrate

animals. These provide tantalizing suggestions regarding their possible homology and make it possible to sketch the evolution of these cells through the major lines of multicellular animals. It is, however, still not possible to be sure whether all these cell types, in every organism, are derived from a common ancestor or whether the strong similarities they show are at least in some cases the result of developmental and physiological constraints. As so often in science, more data, especially from the less-studied invertebrates such as mollusks, will resolve this question.

Glossary

atympanate Refers to the condition of lacking a tympanal ear. Compare with tympanate.

campaniform sensillum A dome-shaped sensory organ normally occurring near joints. Campaniform sensillae are sensitive to distortion of the cuticle as typically occurs during joint movement. Each campaniform sensillum has a single mechanoreceptor cell associated with it.

chitin A major component of arthropod cuticle composed of amino-polysaccharide subunits of acetylglucosamine and glucosamine.

chordotonal organ A mechanosensory organ found in arthropods that functions primarily in detecting body movements and sound vibrations. A type of proprioceptive stretch receptor in arthropods consisting of thin, elastic strands of connective tissue stretched between adjacent body regions and comprised of individual mechanosensory units called scolopidia. Also called chordotonal sensillae.

cuticle The external layers of the integument of arthropods. It is secreted by the epidermis and is comprised of chitin and protein. Cuticle forms the arthropod exoskeleton.

exteroceptor A sense organ that responds to stimuli originating outside the body.

johnston's organ A sensory organ found within the antennal pedicel (second segment of the antennae) of many insects. It comprises several hundred chordotonal sensillae. The organ is stimulated by movements of the antennal flagellum typically in response to near-field sound or vibration.

mechanoreceptor A class of receptor whose adequate stimulus is a physical change in the position of a body part or surface. The mechanical deformation causes an electrical change within the receptor cell (i.e., the generator or receptor potential), and eventually an action potential in the nerve fibre(s) connected to the receptor organ.

proprioceptor A type of mechanoreceptor that provides information to an animal about the position and motion of the body and its appendages.

scolopidia (scolopidium) The individual mechanosensory receptor unit of an insect auditory organ that consists of a linear chain of four cell types: (1) one or more bipolar neurons, (2) a scolopale cell that forms a lumen around the cilium of the neuronal dendrite and whose cytoplasm contains electron-dense scolopale rods, (3) attachment cells that mechanically anchor and support the scolopale cell, and (4) accessory cells that envelop and provide nutritive and mechanical support to the neuronal soma.

spiracle An external opening of the trachea (insect respiratory system).

subgenual organ A chordotonal organ on the proximal tibia (fourth segment of the insect leg) that detects substrate vibration.
trachea (pl. tracheae) An internal component of the insect gas-exchange system; a tubular structure originating at the spiracles (specialized integumentary structures) and most typically branching extensively forming tracheoles within the insect body. Tracheae may be expanded to form air sacs in certain regions of the body.
trichoid sensilla A hair-like projection of the cuticle. Also called a hair, seta, or macrotrichium.
tympanal organ A type of mechanoreceptor used to detect acoustic signals. It is normally associated with a thinned region of cuticle – the tympanic membrane – whose motion directly corresponds to the pressure changes of an acoustic stimulus in the surrounding medium.
tympanate The condition of possessing a tympanal ear or organ. Compare with *atympanate*.

3.02.1 Introduction

An acoustic sense is well developed in many insects. Sounds and vibrations play key roles in detecting and evading predators, locating and choosing mates, establishing territories, forming and maintaining groups, coordinating social interactions, and locating hosts. Insects possess an impressive diversity of different hearing organs, which can be located on almost any part of the body. When discussing an acoustic sense in vertebrates, we typically refer to one type of hearing organ, ears, which are located on the head, and capable of detecting minute time-varying pressure changes transmitted through air or water. In insects however, an acoustic sense is not confined to the detection of sound-pressure waves, but also encompasses the detection of particle displacements, and in the broadest sense, solid-borne vibrations. Therefore, before discussing insect ears it is prudent to begin with a brief overview of the three kinds of acoustic stimuli important to insects: airborne sounds in the nearfield and farfield; and seismic, or solid-borne vibrations.

When a sound-producing source, like a speaker, vibrates back and forth, the molecules of the medium (air or water) in front of the source are displaced and transmit a disturbance to neighboring particles. In the acoustic nearfield, where the distance from the sound-producing source is less than the wavelength, there is a large particle velocity component which is out of phase with pressure. These particle displacements can be sufficient to move a lightweight structure, such as a hair or antenna. We call these nearfield sound receptors, movement receivers, or displacement receivers (Michelsen, A. and Nocke, H., 1974; Bennet-Clark, H. C., 1984; Römer, H. and Tautz, J., 1992). The speaker movement also causes fluctuations in air pressure that are propagated away from the speaker as a pressure wave. We call this the acoustic farfield, where the distance from the source is greater than the wavelength, and particle velocity is in phase with pressure. The pressure component of sound is detectable by farfield sound receptors, typically referred to as tympanal ears or tympanal organs, which can be either pressure-sensitive or pressure-gradient sensitive (Römer, H. and Tautz, J., 1992; Yager, D. D., 1999a; Yack, J. E., 2004). Finally, there is an increasing body of literature demonstrating that many adult and larval insects communicate using solid-borne (seismic) vibrations that are transmitted through sand, leaf litter, or living plant material. Although vibrational communication is often omitted from discussions of ears and hearing, in insects, inclusion of this topic is important since there are many similarities between structures that detect sound and vibrations. We felt that a review of insect hearing would be incomplete without a brief discussion of this sensory modality.

There are several comprehensive reviews on insect hearing organs (Michelsen, A. and Larsen, O. N., 1985; Römer, H. and Tautz, J., 1992; Hoy, R. R. and Robert, D., 1996; Field, L. H. and Matheson, T., 1998; Yager, D. D., 1999a; Mason, A. C. and Faure, P. A., 2004; Yack, J. E., 2004). The goal of this chapter is to present an overview of the structure and diversity of insect sound and vibration receptors, and to highlight some interesting examples among the various insect groups. Special emphasis will be placed on tympanal hearing, since this is where most research has been focused to date. Auditory processing at the level of the central nervous system is not covered here (reviews of this subject can be found in writings by Boyan, G. S., 1993; Pollack, G. S., 1998; 2000;

Stumpner, A. and von Helversen, D., 2001; Hennig, R. M. *et al*., 2004; and Wyttenbach, R. A. and Farris, H. E., 2004).

3.02.2 Tympanal Ears

Tympanal hearing is the best-described acoustic sense in insects, owing to the fact that the behaviors (e.g., singing crickets and cicadas), and receptor organs (tympanal membranes) associated with farfield sound communication are often conspicuous to humans. Tympanal ears are similar to vertebrate ears in that they employ a tympanal membrane (eardrum) to detect pressure changes transmitted through the air (or water). Unlike for vertebrates, however, insect tympanal ears can occur on almost any part of the body, and have evolved multiple times within and between various taxa (Figure 1). Many ears described to date are located at the thoracic-abdominal juncture

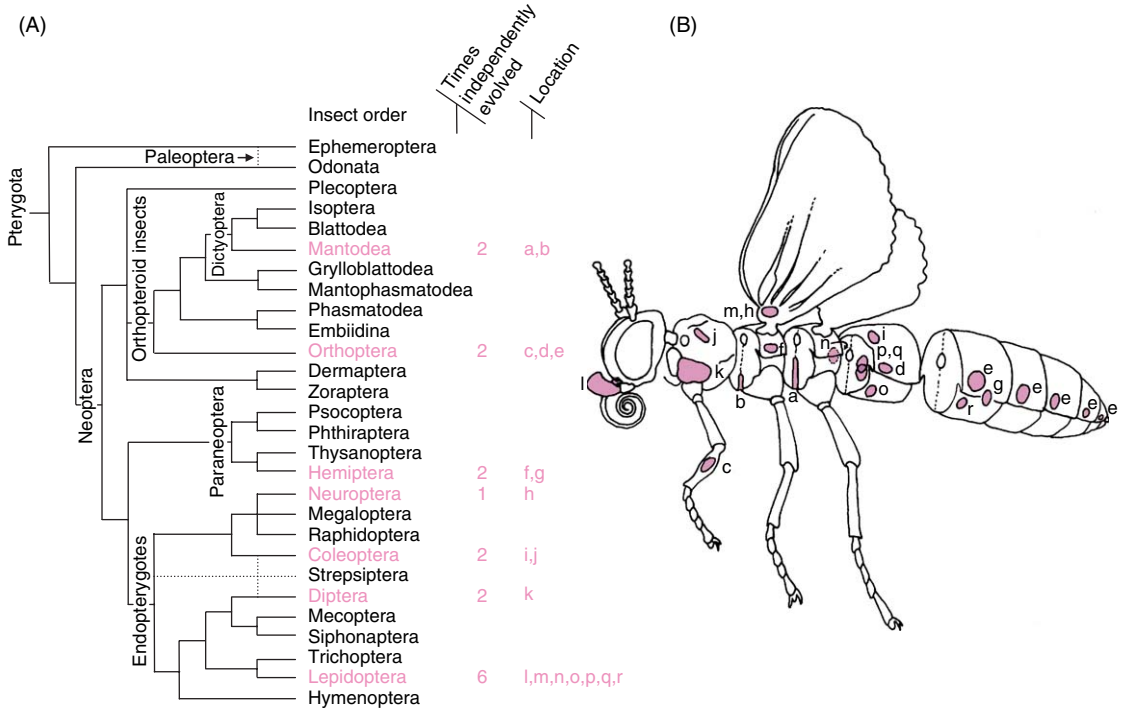

Figure 1 Distribution of tympanal hearing organs in insects. (A) A phylogeny of insects depicting the orders in which tympanal ears have evolved in at least some families. Numbers indicate how many times ears evolved independently within the order, and letters indicate where ears are located on the body, as shown in the drawing on the right. (B) A schematic drawing of a generalized insect showing where tympanal ears occur on insects. Please note that the sizes of the ears on figure are not to scale. Specific body locations according to each taxonomic division are as follows. *Mantodea*: (a) Within a deep groove on the ventral metathorax in many species; (b) In the same position on the mesothorax in Hymenopodidae. *Orthoptera*: (c) Ensifera, Gryllidae, Tettigoniidae. On the tibia of foreleg; (d) Acrididae. Within a tympanal cavity on the first abdominal segment; (d, e) Pneumoridae. On abdominal segment 1 (homologous to (d) in the Acrididae), and serial homologs on segments 2–6. *Hemiptera*: (f) Hydrocorisae. Lateral mesothorax, ventral to wing base; (g) Cicadidae. Within a cavity on the second abdominal segment. *Neuroptera*: (h) Chrysopidae. Base of ventral forewing. *Coleoptera*: (i) Cicindelidae. Dorsal surface of first abdominal segment, beneath the elytra; (j) Scarabidae. Dorsolateral region of prosternum. *Diptera*: (k) Sarcophagidae, Tachinidae. Ventral inflation of prosternum, between coxa (probably evolved independently in both groups). *Lepidoptera*: (l) Sphingidae (Choerocampini, Acherontini). Palp-pilifer region (probably evolved independently in both groups); (m) Papilionoidea, Hedyloidea. Ventral base of forewing (may have evolved independently in both groups); (n) Noctuoidea. Within a cavity on the posterior metathorax; (o) Pyraloidea. Within a cavity on ventral surface of first abdominal segment; (p) Geometridae. Within a cavity on anterior side of first abdominal segment; (q) Drepanidae. Internalized tympanal membrane located between two air-filled chambers on the first abdominal segment. (r) Uraniidae: within a cavity at the anterior (females) or posterior (males) end of the second abdominal segment. Phylogeny in (a) is from Gullan, P. J. and Cranston, P. S. 2005. The Insects: An Outline of Entomology, 3rd edn. Blackwell Publishing. (b) Redrawn from Yack, J. E. and Hoy, R. R. 2003. Hearing. In: Encyclopedia of Insects (*ed*. V. Resh and R. Cardé), pp. 498–505. Academic Press/Elsevier Science, with permission from Elsevier Science Publishers Ltd.

(the waist region of insects), but they also occur on more unusual body parts, including the neck area (some flies and beetles), the wings (some butterflies and lacewings), legs (crickets and katydids), and even the mouth-parts (some moths). Ears range in complexity, from those in notodontid and sphinx moths that possess a single auditory sensory cell (Surlykke, A., 1984; Göpfert, M. C. and Wasserthal, L. T., 1999), to those in some cicadas and bladder grasshoppers that can have up to 2000 sensory cells (Michel, K., 1975; Doolan, J. M. and Young, D., 1981; van Staaden, M. *et al.*, 2003). Tympanal ears in different insects are sensitive to a broad range of sound frequencies (~500 Hz to >100 kHz) at distances reaching up to 2 km. They have been reported in seven insect orders to date, and within most of these orders, ears have evolved more than once. Interestingly, some mantids and grasshoppers have multiple sets of ears on their bodies (discussed in Section 3.02.2.2). It is surprising that tympanal ears have not been reported for the large-bodied Odonates (dragon and damselflies), Hymenoptera (wasps, bees, ants), or Trichoptera (caddisflies), but it is expected that it is only a matter of time before hearing is described in at least some members of these groups.

Despite the wide diversity observed in their location and complexity, most tympanal ears follow a typical morphological plan, which includes three main components: (1) a tympanal membrane, (2) tracheal air sacs, and (3) a chordotonal organ (Figure 2). The tympanal membrane is a thinned region of cuticle, usually round or oval in shape, that is apposed to a tracheal air sac. When sound waves impinge upon the membrane, the auditory chordotonal organ, which is either directly or indirectly attached to the membrane, is stimulated by the vibration. The membrane thickness can vary from 0.4 μm in some noctuid moths (Ghiradella, H., 1971) to 100 μm in some wetas (Ball, E. E. and Field, L. H., 1981), and the diameter can range from ~500 μm (e.g., Hedylid butterflies; Yack J. E. and Fullard, J. H., 2000) to ~4 mm (e.g., some cicadas; Young, D. and Hill, K. G., 1977). In general, thinner membranes tend to be associated with sensitivity to higher frequencies. Finally, not all functional tympanal ears possess clearly differentiated tympanal membranes upon visual inspection of the insect (e.g., mantids, bladder grasshoppers, drepanid moths). A few of these examples will be discussed in this chapter.

The internal face of the tympanal membrane is directly adjacent to an air-filled chamber (tympanal

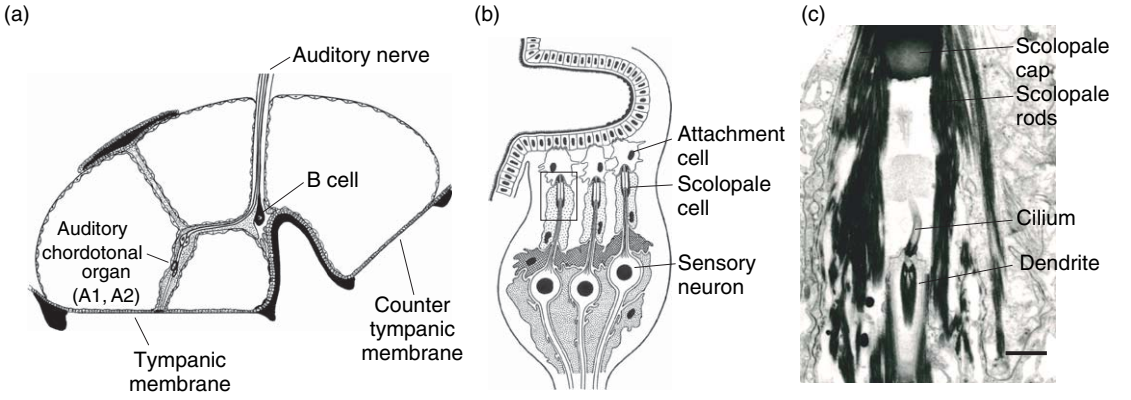

Figure 2 The principle features of a typical insect tympanal ear. (a) A cross section through the ear of a noctuid moth, illustrating the three main components of a tympanal hearing organ: the tympanic membrane, auditory chordotonal organ (which in this case has two scolopidia), and the tracheal air sac (white region). Another cell in the ear, the B cell, is a mutliterminal sensory neuron that does not respond to sound, and at present, the function is unknown. (b) A schematic of a chordotonal organ containing three monodynal, mononematic scolopidia. Each scolopidium comprises a single bipolar sensory neuron with a ciliated dendrite that inserts distally into a scolopale cap. A scolopale cell envelops the dendrite, and an attachment cell connects the entire structure to the integument. The boxed region is enlarged in (c). (c) Transmission electron micrograph of the distal dendritic region of a scolopidium. The ciliary segment passes through a lumen created by the surrounding scolopale cell, and inserts distally into the scolopale cap. Scolopale rod material, located inside the scolopale cell, surrounds the lumen. Scale bar = 0.5 μm. (a) Redrawn from Treat, A. E. and Roeder, K. D. 1959.A nervous element of unknown function in the tympanic organ of moths. J. Insect Physiol. 3, 262–270, with permission from Elsevier Science Publishers Ltd. (b) Reproduced from Gray, E. G. 1960. The fine structure of the insect ear. Phil. Trans. R. Soc. Lond. 243, 75–94. (c) Adapted from Yack, J. E. and Roots, B. I. 1992. The metathoracic wing-hinge chordotonal organ of an atympanate moth, *Actias luna* (Lepidoptera, Saturniidae): a light- and electron-microscopic study. Cell Tiss. Res., 267, 455–471.

chamber) formed by an enlargement of the trachea (part of the respiratory system of insects). The air chamber has an acoustic impedance matched to the external medium on the outside of the eardrum, allowing the membrane to vibrate (Figure 2(a)). In vertebrates, this impedance-matching is achieved by the air-filled middle ear. Although the tympanal chamber is almost always air-filled in insects, there is at least one exception in the green lacewing, *Chrysoperla carnea* (Chrysopidae) (Miller, L. A., 1970) where the ear is largely fluid-filled.

All insect tympanal ears described to date are innervated by a particular class of mechanoreceptors called chordotonal organs, which are unique to the Insecta and Crustacea (Howse, P. E., 1968; Moulins, M., 1976; Field, L. H. and Matheson, T., 1998). In insects, chordotonal organs are located throughout the body, and depending on their location and peripheral attachment sites, may function as proprioceptors (detecting self-induced movements of limbs and internal organs), or exteroreceptors (detecting gravitational forces, sounds, or vibrations). Chordotonal organs are structurally complex, and can be categorized into different morphological types. Briefly, each chordotonal organ comprises one or more units called scolopidia, and each scolopidium is made up of four cell types: (1) one to four bipolar sensory neurons, each with a distal dendrite that contains a modified stereocilium of the $9 \times 2 + 0$ type; (2) a scolopale cell that envelops the distal region of the sensory cell and dendrite and connects the attachment cell to the sensory cell; (3) one or more attachment cells that connect the scolopidium to the integument; and (4) one or more glial cells surrounding the sensory neuron cell bodies. Although little is known about how scolopidia transduce mechanical energy into electrical impulses of the sensory neuron, it is generally believed that longitudinal stretching of the dendritic cilium leads to permeability changes of the sensory cell at the base of the cilium. There is significant variation in the structure of chordotonal organs and their constituent scolopidia, and presumably these structural variations impart different functional characteristics to the sense organ.

Without exception, all chordotonal organs innervating insect tympanal ears (tympanal organs) that have been studied to date have certain ultrastructural features in common (Figures 2(b) and 2(c)). First, they are of the mononematic type, characterized by having an extracellular structure called a scolopale cap at the terminal end of the dendritic cilium. Second, they are of the monodynal type, meaning that there is only one dendrite associated with each scolopidium. Third, they possess type 1 scolopidia, which are distinguished by having a ciliary segment that has uniform diameter. At present, the functional importance of these ultrastructural features consistently found in tympanal organs is not understood. However, they are thought to be important for imparting a high degree of coupling between the vibrating membrane and the sensory cell, which would be a necessity for detecting small, rapid sound vibrations (Yack, J. E., 2004). While some structural features of tympanal organs are consistent, others, such as the number of scolopidia in the organ, or how the chordotonal organ is associated with the tympanal membrane, are variable. For further reading on the structure and function of chordotonal organs in general, the reader should consult Howse P. E. (1968), Moulins M. (1976), and Field L. H. and Matheson T. (1998). More specific reviews of chordotonal organs associated with insect hearing include the ones by Field L. H. and Matheson T. (1998), Eberl D. F. (1999), Yager D. D. (1999a), and Yack J. E. (2004).

3.02.2.1 Evolutionary Origins of Tympanal Ears

Why do insect tympanal ears occur in so many different body locations? One argument is that for insects, it is relatively easy to make an ear. There are now several lines of evidence demonstrating that tympanal ears evolved from chordotonal organs that previously served another function. As mentioned earlier, chordotonal organs occur throughout the insect body, where they commonly function as proprioceptors. It appears that through changes to peripheral structures associated with the chordotonal organ, a chordotonal organ that previously responded to proprioceptive or vibrational stimuli can be rendered sensitive to airborne vibrations, and thus converted to a hearing organ. Specific peripheral changes associated with the transition from proprioception to hearing might include the thinning of cuticle (i.e., development of a tympanum), enlargement of trachea, and other cuticular modifications that isolate the chordotonal organ from mechanical disturbances due to body movements. Support for the hypothesis that the evolutionary precursors of insect tympanal organs were vibration receptors or proprioceptors comes from comparative and developmental studies. For example, comparisons between primitively atympanate and tympanate moths show that the ultrasound sensitive thoracic ears of Noctuoid moths probably evolved from wing proprioceptors (Yack, J. E. and Fullard, J. H., 1990; Yack, J. E. *et al.*,

1999). Developmental studies on the abdominal ear of the locust demonstrate that the tympanal organ derives from an embryonic pleural chordotonal organ that monitors respiratory movements (Meier, T. and Reichert, H., 1990).

In discussing the transition from proprioception or vibration reception to hearing, many interesting questions arise. What are the genetic mechanisms governing the developmental processes leading to changes in peripheral structures, such as differences in the number of scolopidia, enlargement of tracheal air sacs, and the formation of a tympanal membrane? How is the wiring of the central nervous system modified for the animal to execute behaviors associated with hearing, such as positive phonotaxis, or evasive flight maneuvers? Why did ears evolve to be on any one particular body part in any given insect? Discussions of the developmental and evolutionary origins of insect tympanal ears are presented in research by Fullard J. H. and Yack J. E. (1993), Yack J. E. and Fullard J. H. (1993), Yager D. D. (1999a), Hasenfuss I. (2000), van Staaden M. *et al.* (2003), and Yack J. E. (2004).

3.02.2.2 Which Insects Have Tympanal Ears?

Tympanal ears are estimated to have evolved independently at least 17 times in insects (Figure 1), and this is not accounting for examples such as the multiple ears in bladder grasshoppers (van Staaden, M. *et al.*, 2003), or morphologically distinct tympanal membranes in some Lepidoptera that have not as yet been experimentally verified as functional hearing organs (Minet, J. and Surlykke, A., 2003). Even so, tympanal ears to date have only been described in seven of the 26 widely recognized extant neopteran insect orders. Why is it that some insect groups tend to be well equipped with ears, while others are deaf? A first answer is relatively clear to us, and this is that insect groups with members that are nocturnal and volant tend to have more members with ears. A great selection pressure for ear development arose about 60 million years ago, when bats began to use echolocation to detect their prey (Fullard, J. H., 1998), and this explains the origin of hearing in many insects, including moths, beetles, mantids, and lacewings. Lifestyle may explain why we do not see tympanal ears in some groups. For example, some insects that are nocturnally active may have alternative defense strategies. Mayflies, for example, are very short-lived as adults and synchronize their emergences to swamp their predators. Social Hymenoptera may lack tympanal hearing organs for communication purposes because of their communal lifestyle and the efficiency of near-field acoustic and substrate vibrations within a hive. Body size may also be an important factor in determining which insects have tympanal ears. Large insects may lack ears because their size offers some protection from bats (e.g., large silk- and hawk-moths, and dragonflies). In contrast, very small insects generally lack tympanal ears, and this could be for a couple of reasons. First, it is unlikely that a small-sized insect would use farfield sounds for communication because it would not have the mechanical power to generate sounds that will carry long distances (Bennet-Clark, H. C., 1998). Second, there is likely a size limit to how small an ear can be and still be functional. It could be that there is a minimum body size that can accommodate an ear, and that acoustic communication among small-bodied insects is restricted to the domain of solid-borne vibrations. The topic of ear size, with respect to the constraints imposed on miniature auditory systems and the selection pressures shaping ear size, is an interesting one (Surlykke, A. *et al.*, 1999; Robert, D., 2001). Following is a concise overview of tympanal ears described to date in the seven recognized tympanate insect orders.

3.02.2.2.1 Lepidoptera

Tympanal ears have evolved independently a minimum of six times in the Lepidoptera (moths and butterflies), where they are located on the thorax (Noctuoidea), abdomen (Pyraloidea, Geometroidea, Drepanoidea), mouth-parts (Bombycoidea), and wings (Hedyloidea, Papilionoidea). In addition, some members of the Tineoidea, Cossoidea, and Thyridoidea are likely to have ears, but confirmation of hearing in these groups awaits physiological and/or behavioral validation. All moth ears studied to date are sensitive to ultrasound (>20 kHz), and in most cases, function primarily as bat detectors (Miller, L. A. and Surlykke, A., 2001; Minet, J. and Surlykke, A., 2003). In species that also produce sounds, including some day-flying tiger moths (Arctiidae), hearing has secondarily assumed a role in social interactions (Spangler, H. G., 1988; Conner, W. E., 1999). Sonic hearing (<20 kHz) has only been demonstrated in a few species of Nymphalidae butterflies to date, and is believed to be used for conspecific communication and possibly the detection of bird predators (Ribaric, D. and Gogala, M., 1996; Yack J. E. *et al.*, 2000; Yack J. E., unpublished). The structure and function of moth ears has been studied extensively, and recently reviewed (Minet, J. and Surlykke, A., 2003). We restrict our

description of lepidopteran ears to two moth groups, the Noctuoidea, which have a very simple ear, and the Drepanoidea, which have a morphologically unconventional tympanal ear.

Noctuoidea ears are among the simplest of all insect ears studied to date, with only one (Notodontidae) or two (all other families) auditory cells (Figures 2(a) and 3). The ears are located on the posterior metathorax, nestled within a protective tympanal cavity (Figure 3(a)). The eardrum is an extremely thin (~0.4–1.0 μm) transparent membrane, bordered by a chitinous ring, and stretched across an enlarged tracheal air space, the tympanic chamber (Figure 3(b)). The tympanal organ attaches directly to the inner surface of the tympanal membrane. In those ears with two auditory cells (A1 and A2), both cells are broadly tuned to the same frequencies (25–50 kHz), but differ in their sensitivities by approximately 20 dB. The sensitivity range of moth ears overlaps with the same frequencies produced by the echolocation cries of

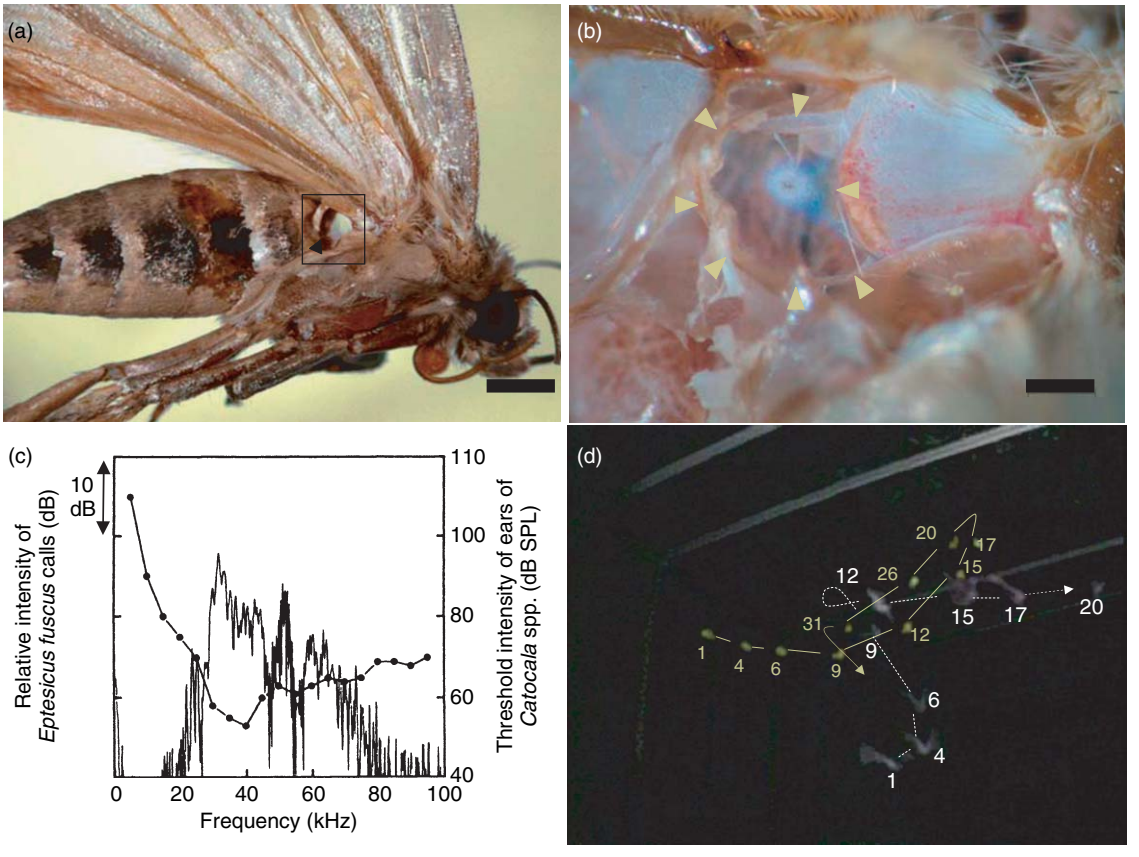

Figure 3 Hearing in noctuoid moths. (a) Photograph of the copper underwing moth, *Amphipyra pyramidoides,* indicating the location of the ear (boxed region) within a cleft at the junction of the thorax and abdomen (arrowhead). Scale bar = 3 mm. (b) Photograph showing the counter- tympanic membrane (indicated by arrowheads) and countertympanic membrane (translucent region to right of tympanic membrane). The attachment site of the auditory chordotonal organ appears as a small circular region of translucency and is partially visible through the courter-tympanic membrane. Scale bar = 500 μm. (c) Tuning curve of the A1 auditory receptor cell (filled circles) of an underwing moth (*Catocala* spp.) showing greatest sensitivity to sound pulses with 40 kHz carrier frequencies. The echolocation calls of the big brown bat, *Eptesicus fuscus*, a predator of underwing moths, have substantial energy in the 30–70 kHz band, the frequencies to which the ear of the moth is most sensitive. (d) A photo-montage created from a video capturing the interaction between a noctuid moth (dots and solid line highlighted in yellow) (unknown species) and a little brown bat, *Myotis lucifugus* (in gray with broken line). The moth is seen making changes in direction in response to the echolocation calls and flight path of the bat. Numbers indicate video frames compiled into the montage. (a, b) Photographs by J. Dawson. (c) Reproduced from Fullard, J. H. and Yack, J. E. 1993. The evolutionary biology of insect hearing. Trends Ecol. Evol. 8, 248–252, with permission from Elsevier Science Publishers Ltd. (d) Unpublished data by J. Dawson and A. Soutar.

insectivorous bats (Figure 3(c)). Flying moths stimulated with ultrasound respond by either turning away from the bat (negative phonotaxis), or engaging in an erratic evasive flight maneuver (Figure 3(d)) (reviewed by Roeder, K. D., 1967; Fullard, J. H., 1998; Miller, L. A. and Surlykke, A., 2001). This bi-modal response has in the past been attributed to the different thresholds of the two auditory cells. The lower threshold cell (A1) is thought to alert the moth to a far bat, and initiate negative phonotaxis, while the higher threshold cell (A2) warns of a close bat, to elicit evasive flight maneuvers. However, the jury is still out on how each of these cells contributes to evasive flight maneuvers (Fullard, J. H. *et al.*, 2003). Sound localization in moths can be achieved by comparing differences in sound intensities reaching each ear, since the wavelengths of the high-frequency sounds detected by moths are short enough to be diffracted by the moth's body.

The ears of hook-tip moths (Drepanoidea) are worth mentioning as a variation on the typical morphological plan of tympanal ears (Surlykke, A. *et al.*, 2003). In these moths, the eardrum is not directly exposed to the moth's exterior. Rather, the tympanal membrane occurs inside of the moth, stretched across an opening that joins two enlarged air-filled chambers (the dorsal chamber (dc) and ventral chamber (vc) in Figure 4). The scolopidia, instead of being attached to the tympanal membrane in a perpendicular orientation, as in the noctuid ear, are sandwiched between the tracheal air sac in the ventral chamber, and the tympanal membrane. It is believed that sound reaches this internal tympanum by two external membranes (anterior and posterior external membranes), and that the scolopidia are stretched lengthwise when sound impinges on the membrane. Like other moth ears, the drepanid ear is tuned to ultrasound, and represents another unique means by which insects have formed a high-frequency ear.

3.02.2.2.2 Orthoptera

Hearing has evolved independently in the suborders Caelifera (grasshoppers, locusts) and Ensifera (crickets, katydids, and wetas). In contrast to the Lepidoptera, the primary function for hearing in extant Orthoptera is conspecific communication, and secondarily, for predator detection.

In most grasshoppers and locusts, the ears are conspicuous, circular, translucent membranes located on the sides of the first abdominal segment (Figures 5(a) and 5(b)). The tympanal chordotonal organ (Müller's organ) attaches directly to the inner surface of the tympanum, and contains between 60 and 80 scolopidia, which are divided into groups (a, b, c, d) that attach to different parts of the membrane (Figure 5(d)) (Gray, E. G., 1960; Michel, K. and Petersen, M., 1982; Jacobs, K. *et al.*, 1999). The acridid ear is one of the few insect ears capable of pitch discrimination (Figure 5(c)). The mechanism has been explained by the place principle of frequency discrimination, whereby the tuning of the different cell groups is achieved by the unique resonance properties of the tympanal membrane to which they attach, and Müller's organ itself. This is similar to frequency discrimination in the mammalian cochlea where a traveling wave in the basilar membrane stimulates hair cells selectively.

Evidence for hearing in a primitively atympanate insect, the bladder grasshopper (*Bullacris membraciodes*) of South Africa, has made us reconsider our definition of tympanal hearing organs, since generally the term tympanal ear implies that the insect has an eardrum of some sort. These insects are highly acoustic, producing loud calls by which males and females 'duet' across distances up to 2 km. Bladder grasshoppers do not possess conspicuous tympanal membranes at all, but rather, have six pairs of abdominal chordotonal organs that are sufficiently sensitive to detect conspecific calls (van Staaden, M. J. and Römer, H., 1998; van Staaden, M. *et al.*, 2003) (Figures 5(e)–5(h)). Each ear of the most anterior pair of ears (on segment A1) comprises a large chordotonal organ with ~2000 scolopidia. The A1 chordotonal organ in bladder grasshoppers is homologous to Müller's organ in locusts, but in contrast to the latter, lacks an association with a tympanal membrane, and possesses far more scolopidia. In addition to the A1 ears, five simpler, serially homologous chordotonal organs with 11 scolopidia each, occur in the posterior segments A2–6. All of these chordotonal organs attach to thinned regions of cuticle on the body wall, and are sensitive to the sound frequencies and intensities of conspecific calls, despite the absence of a differentiated tympanal membrane. The bladder grasshopper is considered to represent a relatively ancient group of Acrididae, and it is argued that their hearing organs represent a living example of the evolutionary transition between proprioceptors and tympanal hearing.

Ears of crickets (Gryllidae) and katydids (Tettigoniidae) occur on the proximal tibia of the forelegs. There are two oval-shaped tympanal membranes on each leg – one on the front and one on the back. Each tympanum is apposed to a tracheal air sac, which

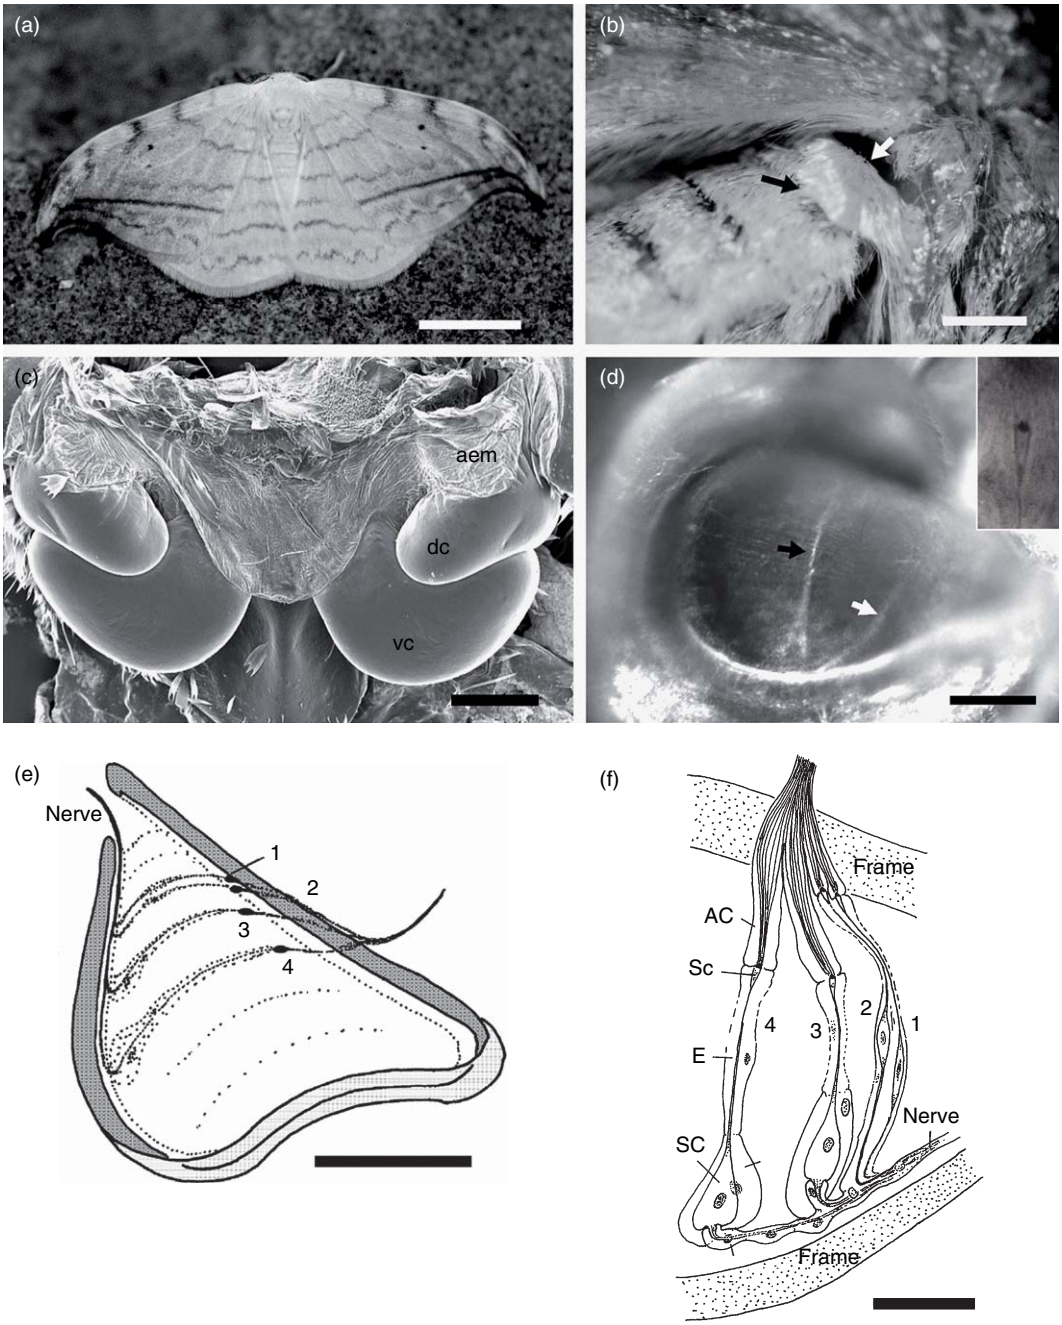

Figure 4 Tympanal ears in a hooktip moth (Drepanoidea). (a) A *Drepana arcuata* moth. Scale bar = 6 mm. (b) Right lateral view of the thorax and anterior abdomen, showing the general location of the abdominal ear. A white arrow points to the location of the anterior external membrane (aem in (c)), and a black arrow points to the location of the posterior external membrane. Scale bar = 0.75 mm. (c) Scanning electron micrograph of the anterior and ventral portion of the first abdominal segment. Each ear comprises a dorsal (dc) and ventral (vc) air chamber, between which the tympanal membrane is located. Sound is thought to enter the dorsal chamber by means of the anterior and posterior external membranes. Scale bar = 0.25 mm. (d) The internal tympanal membrane of the left ear as seen following removal of the dorsal chamber. Four scolopidia are suspended between the two tracheal sheets forming the tympanal membrane. The black and white arrows mark the location of scolopidia 4 and 3 respectively. Scale bar = 80 μm. The inset shows the distal tip of a scolopidium. (e) Drawing of the tympanic membrane with scolopidia 1–4 viewed from the dorsal chamber. Scale bar = 0.1 mm. (f) Further details of the tympanal scolopidia. SC, sensory cell; E, enveloping (scolopale) cell; Sc, scolopale region; AC, attachment cell. Scale bar = 0.05 mm. Reproduced from Surlykke, A., Yack, J. E., Spence, A. J., and Hasenfuss, I. 2003. Hearing in hooktip moths (Drepanidae, Lepidoptera). J. Exp. Biol. 206, 2653–2663.

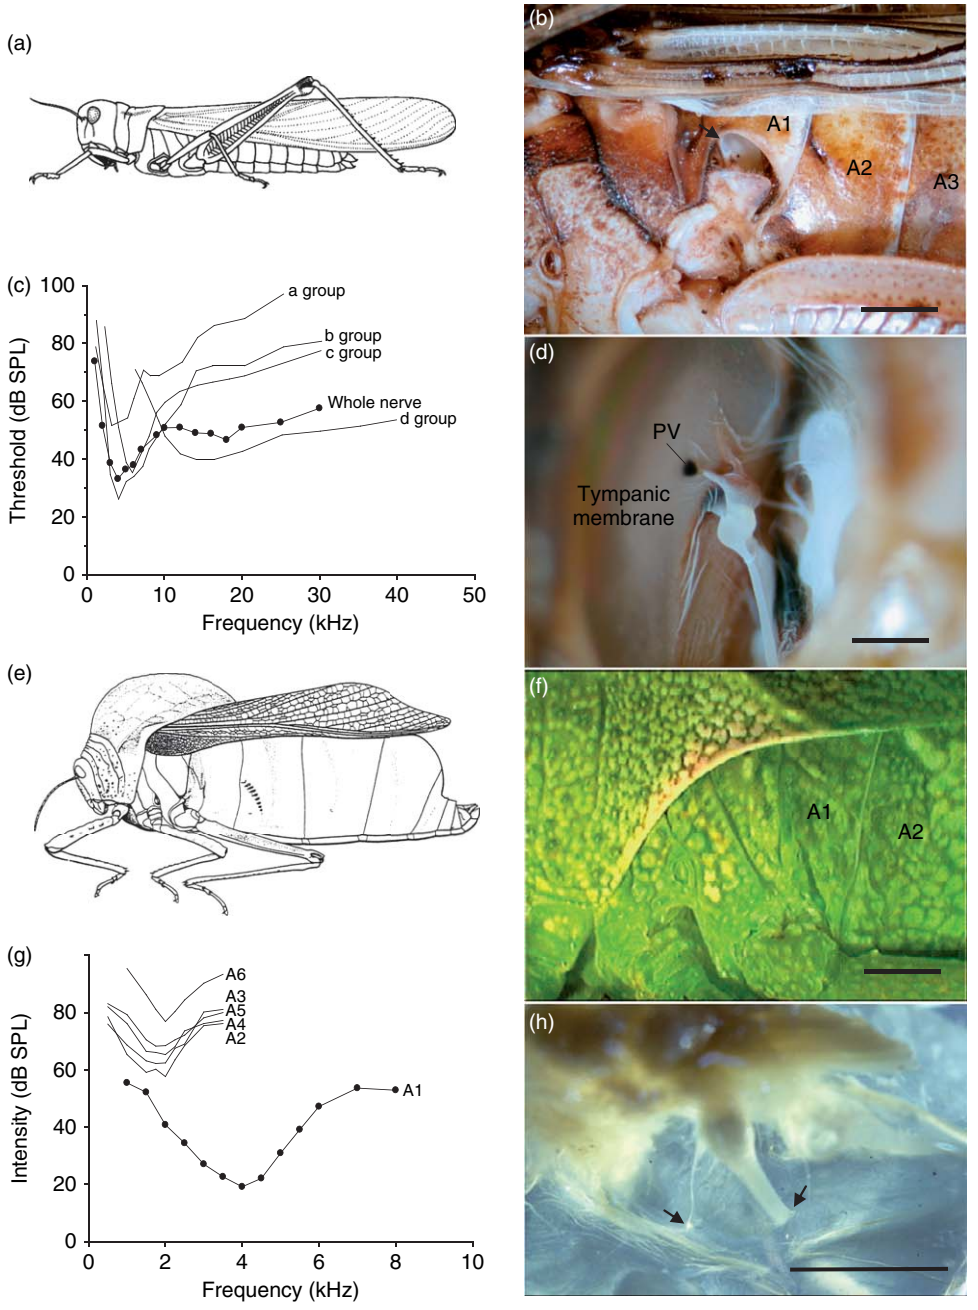
in turn, is connected to other sound input sources, such as spiracles, and ears on the contralateral side of the body. In many insects, like the cricket, that use low-frequency sounds for communication, sound localization is a problem because the wavelength of the sound is greater than the width of the body (unlike for the noctuid moth, discussed earlier). Crickets solve this problem by having pressure-gradient ears, whereby the sound stimulates the tympanic membrane via both external and internal routes. In crickets, the tympanal membrane vibrates in response to sound reaching the ear from the external side of the



tympanum, but also from sounds that reach the inner side of the membrane by ipsilateral and contralateral spiracles. Because sound can reach the tympanal membranes from different routes, the relative lengths of the routes introduce phase delays between the ears, which provide directional cues for sound location.

In most Ensifera, the tympanal organ does not attach directly to the tympanal membranes, but rather, to the tracheal sac that lies adjacent to the anterior tympanal membrane. The scolopidia (60–70 in crickets, 20–50 in katydids) are arranged in a row down the leg, and are tonotopically organized, with the more distal units responding to higher frequencies (Stumpner, A., 1996). At present, the mechanism underlying the tuning properties of ensiferan ears is unknown, and there is experimental support that both intrinsic properties of the scolopidia themselves, and peripheral structures, such as trachea and membranes, play a role (see discussions by Field, L. H. and Matheson, T., 1998; Pollack, G. S. and Imaizumi, K., 1999). More extensive coverage of hearing in Orthoptera is provided by Michelsen A. and Larsen O. N. (1985), Ball E. E. *et al.* (1989), Bailey W. J. (1990), Field, L. H. and Matheson, T. (1998), and Yager D. D. (1999a).

3.02.2.2.3 Hemiptera (Homoptera + Heteroptera)

Cicadas (Homoptera, Cicadidae) are familiar to many of us because of the loud, high-pitched buzzing sounds they produce during hot weather. These sounds, usually produced by males calling to females, are generated by tymbal organs on the thorax, and often reach intensities close to 100 dB at close range, equivalent to what one might experience standing near a smoke alarm. Cicada ears comprise a pair of large oval tympanal membranes located inside a protective cavity on the ventral side of the second abdominal segment. The tympanal organ is contained within a sclerotized capsule and attaches to the lateral border of the eardrum. Cicada ears are among the largest of insect tympanal ears with respect to tympanal area (reaching 4 mm^2) and the number of scolopidia (up to 2000 scolopidia per ear). The large number of cells is thought to enhance frequency discrimination, thereby allowing females to exploit additional components of the calling song (Fonseca, P. J. *et al.*, 2000).

Many waterbugs (Heteroptera, subfamily Hydrocorisae) communicate acoustically (Aitken, R. B., 1985) but little is known about how they hear. Only one species, the water boatman, *Corixa punctata*, has been studied in detail. The round tympanal membrane occurs on the lateral mesothorax, between the forewing and the leg. A large club-shaped cuticular structure extends outward from the membrane, and the auditory organ, comprising only two scolopidia, attaches to the base of this club. Surprisingly, the acoustic cells in the left and right ears are asymmetrical in their tuning and thresholds, with the left ear being consistently more sensitive to higher frequencies than the right. These physiological differences have been attributed to differences in vibrational qualities of the tympanal membrane and

Figure 5 Homologous hearing organs in the tympanate African migratory locust, *Locusta migratoria* and the atympanate bladder grasshopper, *Bullacris membracioides*. (a) Line drawing of the gregarious phase *L. migratoria*. (b) Photograph of the thorax and first three abdominal segments (A1–3) of *L. migratoria*. The tympanic membrane is found on the first abdominal segment (arrow) within a recess protected by the tympanal hood. The metathoracic (jumping) leg has been lowered to reveal the ear. Scale bar = 4 mm. (c) Threshold tuning curves from *L. migratoria* recorded from the whole auditory nerve (closed circles) and from individual receptors (a, b, c, and d group) within the auditory nerve (solid lines). (d) The internal surface of the ear of *L. migratoria* showing Müller's organ. The tympanic membrane is composed of both thick and thin membranous areas. The black dot is the pyriform vesicle (PV); the site of attachment of the high-frequency (d group) auditory receptors. Scale bar = 200 μm. (f) Line drawing of *B. membracioides*. (f) The thorax and first two abdominal segments of *B. membracioides* showing the absence of an overt tympanum in the body wall of the first abdominal segment (A1) – compare with B above. Scale bar = 2 mm. (g) Threshold tuning curves recorded from the serially homologous abdominal chordotonal organs in *B. membracioides*. The curve recorded from the first abdominal segment, A1 (11 males and females combined) indicates this organ has lower thresholds than the organs located in abdominal segments 2–6 (A2–6; curves are from a single individual). (h) Internal view of the A1 abdominal segment showing the chordotonal organ with two attachment sites of the sensillae (arrows). This chordotonal organ is much larger with many more sensory cells than that found in Müller's organ in *L. migratoria* (compare with (d)). Scale bar = 1.2 mm. (a) Reproduced from Gullan, P. J. and Cranston, P. S. 2005. The Insects: An Outline of Entomology, 3rd edn. Blackwell Publishing. (b, d) Photographs by J. Dawson. (c) Adapted from Römer, H. 1976. the clubbed structure (Prager, J., 1976; Prager, J. and Larsen, O. N., 1981). The biological significance of this phenomenon is thought to be an accommodation for changes in the resonance properties of the tympanal membrane while the animal is diving (Prager, J. and Streng, R., 1982).

3.02.2.2.4 Diptera

Tympanal hearing in flies does not function for conspecific communication or predator detection, as it does for most insects, but rather, for eavesdropping on the communication signals of other insects. Certain species of parasitoid flies belonging to the families Tachnidae and Sarcophagidae have independently evolved tympanal ears on their prosternum, just behind the head in the neck region of the insect (Figures 6(a) and 6(b)). Hearing is best developed in females, whose ears are tuned to the calling song of their particular host (Figure 6(c)), such as crickets, katydids, and cicadas. Once located, the female fly lays endoparasitic larvae on the host, where the larvae feed until pupation. Female *Ormia ochracea* (Tachinidae, Ormiini) can localize the call of a male cricket in the dark with remarkable accuracy in the absence of visual or olfactory cues (Müller, P. and Robert, D., 2001) (Figure 6(d)). Directional hearing is attributable to a previously undescribed mechanism for sound localization, which involves a unique lever system that amplifies very small time and amplitude differences between the two eardrums. Fly hearing has been reviewed by Robert D. and Hoy R. R. (1998) and Yager D. D. (1999a).

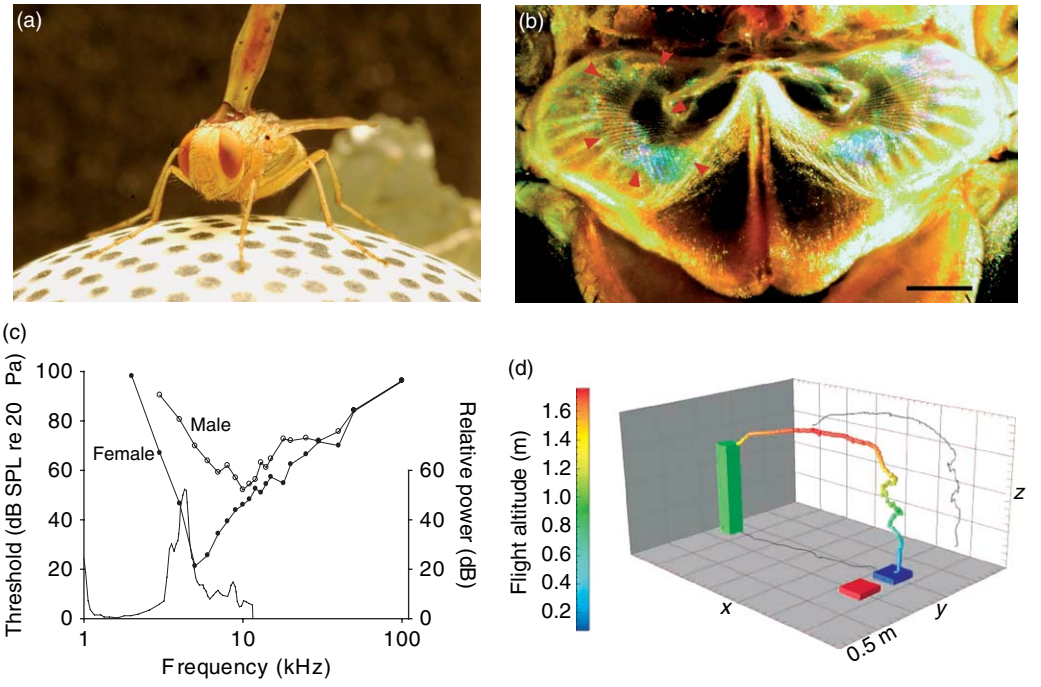

Figure 6 Hearing in the tachinid fly, *Ormia ochracea*. (a) Photograph of a tethered fly on a locomotion-tracking ball. (b) Photomicrograph of the ear. The head has been removed and the reader is looking at the neck region of the fly. The tympanic membrane is the region of thin cuticle outlined by arrowheads. A stiff cuticular rod connects the approximate centre of each tympanic membrane across the midline of the fly. This rod is used to facilitate extraction of directional information from the ear. Scale bar = 200 μm. (c) Threshold tuning curves of female (closed circles) and male (open circles) flies. The ears of females are more sensitive than the males and are frequency-matched to the calling song of their cricket host (solid line). (d) Three-dimensional reconstruction of the phonotactic flight path of a fly approaching a speaker broadcasting a synthesized cricket calling song. The fly takes off from the starting platform (green) and lands on the broadcasting speaker (blue); during the final stages of the approach, the fly exhibits a circling flight path. A shot in the dark: the silent quest of a free-flying phonotactic fly. J. Exp. Biol. 204, 1039–1052.

3.02.2.2.5 Dictyoptera

Praying mantids (suborder Mantodea) were once thought to be deaf, but it is now estimated that hearing occurs in about 65% of all mantid species. The ear is located on the ventral midline of the metathorax, between the legs, inside a narrow groove. The teardrop-shaped eardrums, which are relatively thick (15–20 μm) and stiff compared to many other insect ears, are separated by a space of only 100–200 μm. As such, the mantid has been dubbed the auditory cyclops, and due to the close proximity of the ears to one another, lacks directional hearing. The ears are tuned to ultrasonic frequencies (25–50 kHz), and hearing triggers evasive flight maneuvers to escape bats. Ears are best developed in males, and the degree of sexual dimorphism seen in different species is positively correlated with wing length dimorphism. Interestingly, some species possess an additional set of ears on the mesothorax, which are serial homologs of the metathoracic ear. These are tuned to lower frequency sounds (2–4 kHz), and to date, their function remains a puzzle. Recent reviews of mantid hearing are provided by Yager D. D. (1999a; 1999b).

There is some evidence that *Periplaneta* cockroaches (suborder Blattidae) are capable of detecting farfield sounds below 5 kHz using the subgenual organs in their legs. There are no apparent tympanal membranes, and it is thought that sound arrives to the subgenual organ through the trachea (Shaw, S. R., 1994). There is no obvious function for detecting airborne sounds in *Periplaneta*, but other species, such as the hissing cockroach (*Gromphadorhina*), produce sounds in a social and defensive context, and it is possible that these insects use subgenual organs for communication (Nelson, M. C. and Fraser, J., 1980).

3.02.2.2.6 Coleoptera

Acoustic communication is widespread in beetles, which have a diversity of stridulatory structures that rivals no other insect order (Wessel, A., 2006). Surprisingly, little is known about their capabilities of detecting sounds or vibrations. To date, tympanal ears have been described in certain species belonging to two families. In tiger beetles (Cicindelidae), ears occur on the dorsum of the first abdominal segment in members of only one genus, the *Cicindela* (Yager, D. D. and Spangler, H. G., 1995; 1997; Yager, D. D. *et al.*, 2000). In some scarab beetles (Scarabidae, Dynastinae), ears are located on the anterior thorax, just behind the head (Forrest, T. G. *et al.*, 1995; 1997). In both tiger and scarab beetles, the ears are tuned to ultrasound, and thought to function in bat detection. It is somewhat surprising that hearing has not been discovered in more beetles, given their abundant numbers (350 000 described species) and that many species are nocturnal fliers, and communicate acoustically.

3.02.2.2.7 Neuroptera

Hearing in green lacewings (Chrysopidae) is tuned to ultrasound (30–60 kHz), and functions exclusively in bat detection. When approached by a bat at close range, a lacewing folds its wings and falls to the ground. The ears are located on the ventral forewing at the base of the radial vein, in a similar location described for some butterflies (Yack, J. E. and Fullard, J. H., 2000). The tympanal membrane is not at all conspicuous, but rather, comprises a thin region of cuticle on the ventral aspect of the wing that is associated with two chordotonal organs (Miller, L. A., 1970). Based on morphological evidence alone, one would not expect this organ to function as a hearing organ, yet its role as a bat detector has been indisputably supported through physiological and behavioral experiments. Lacewing ears are among the smallest of known insect ears, ~500–600 μm long, and are mostly fluid-filled. Perhaps the small size of the ear and the problem with impedance matching (due to being fluid-filled) explain its relatively high thresholds (60+ dB SPL at 50 kHz). However, since this functions as a last chance ear, when a bat has already detected and begun its attack upon the insect, such high thresholds are adaptive. Hearing in lacewings has been reviewed by Miller L. A. (1984) and Miller L. A. and Surlykke A. (2001).

3.02.3 Nearfield Sound Receptors

Typical sources of nearfield sounds relevant to insects include those produced by the beating wings of a flying predator or parasite, such as a wasp, or by a singing or flying conspecific. These sounds are typically restricted to lower frequencies (under 1 kHz) and do not travel distances of more than one wavelength from the sound source. For example, if the dominant frequency of the sound is 100 Hz, most of the nearfield component would have dissipated by 3.3 m, while the nearfield component of a 1 kHz sound would have dissipated within 33 mm. The antennae of some insects, including many Diptera (e.g., mosquitoes, fruit flies, and midges) are highly specialized to detect the nearfield sounds generated by the wing-beats of flying or singing mates. In the male mosquito, the long, plumous antennae fit loosely into sockets and resonate freely to frequencies produced by a flying female (Göpfert, M. C. *et al.*, 1999).

Antennal vibrations are transferred to an elaborate chordotonal organ, the Johnston's organ, comprising up to 15 000 sensory neurons (Boo, K. S. and Richards, A. G., 1975), that occurs in the pedicel at the antennal base. Recent studies suggest that nearfield hearing in mosquitoes and fruit flies may be enhanced through autonomous activity of the Johnston's organ, analogous to cochlear amplification in vertebrates (see Göpfert, M. C. and Robert, D., 2001; Göpfert, M. C. *et al.*, 2005). This is an interesting discovery, since hearing in insects has previously been considered to be a passive rather than an active process. There is evidence that nearfield sounds form an important component of the complex dance language of honeybees (*Apis mellifera*), and that these signals are detectable by the Johnston's organ (reviewed by Hrncir, M. *et al.*, 2006) (Figure 7). Some caterpillars use modified seta, called trichoid sensilla, to detect the nearfield sounds produced by flying predatory or parasitic wasps or flies. These elongate hairs insert into specialized sockets on the thorax. Each is innervated by a single bipolar sensory neuron, which is excited by deflection of the sensillum. Vibration of the hair in response to nearfield sounds of an approaching wasp initiates defensive reactions, including cessation of locomotion, squirming, and dropping to the ground. The best-studied example is the cabbage moth caterpillar, *Barathra brassicae* (Noctuidae) (Figure 8). Eight thoracic trichoid receptors project outward from the insect's body, and removal of these hairs abolishes the defensive responses (Markl, H. and Tautz, J., 1975). The trichoid sensillum's best frequency (resonance frequency) is ~150 Hz, the same frequency as the major sound component of the wing beat of *Dolichovespula media* (Hymenoptera: Vespidae), a tiny wasp that lays its eggs in the body of the larvae (Tautz, J. and Markl, H., 1978). The use of nearfield sounds is probably widespread in insects, and should be examined for its role in behavior more extensively. Reviews on the subject include the ones by McIver S. B. (1985), Römer H. and Tautz J. (1992), and Field L. H. and Matheson T. (1998).

3.02.4 Vibration-Sensitive Organs

Although vibrational, or seismic communication, in insects has been recognized for decades, it has often been overlooked, since generally these signals are undetectable by humans. A recent resurgence of literature on the subject is at least partly due to more scientists having access to sensitive vibration-recording methods, such as laser vibrometry. Indeed, seismic communication appears to be widespread among both adult and larval insects, and plays important roles in sexual communication, predator and prey localization, defense, and orientation (see Cocroft, R. B., 2001; Cokl, A. and Virant-Doberlet, M., 2003; Virant-Doberlet, M. and Cokl, A., 2004; Cocroft, R. B. and Rodriguez, R. L., 2005 for recent reviews).

Despite the ubiquitous presence of vibrational communication in insects, little has been reported on the receptor organs used for detecting seismic signals. Trichoid sensilla, campaniform sensilla, Johnston's organs, and scattered chordotonal organs have all been implicated as vibration receptors, but the most widely studied structure to date is the subgenual organ, located in the legs of most insects (reviewed by McIver, S. B., 1985; Field, L. H. and Matheson, T., 1998). These organs are best developed in species that are particularly sensitive to solid-borne vibrations, including some ants (Menzel, J. G. and Tautz, J., 1994), cockroaches (Moran, D. T. and Rowley, J. C. III, 1975), crickets (Friedman, M. H., 1972), wasps (Vilhelmsen, L. *et al.*, 2001), lacewings (Devetak, D. and Pabst M. A., 1994), and honeybees (Hrncir, M. *et al.*, 2006; Figure 7). The structure has probably been best studied in lacewings (*Chrysoperla*) that use vibrations for courtship. In *Chrysoperla carnea*, the attachment cells of the chordotonal organ form a septum that attaches to the walls and trachea of the leg. The scolopidia attach to the septum in a perpendicular orientation, and vibrations of the leg are thought to cause acceleration of the leg hemolymph, causing stimulation the scolopidia.

The subgenual organ has been implicated as the primary receptor in several insect groups that communicate seismically, but in most cases this has not been validated scientifically.

3.02.5 Summary and Future Considerations

Acoustic communication in insects is widespread and involves not only the detection of pressure waves, but also nearfield sounds and vibrational signals. A variety of different sound and vibration receptors have evolved in different insect groups, including tympanal ears, Johnston's organs, trichoid sensillae, and subgenual organs. Collectively, these acoustic sensory organs operate over a frequency range extending up to 150 kHz, and an intensity range of 100 dB. Sound and vibration receptors have evolved multiple times in different insect groups, and this enormous diversity of ear types is partially due to the fact that there are

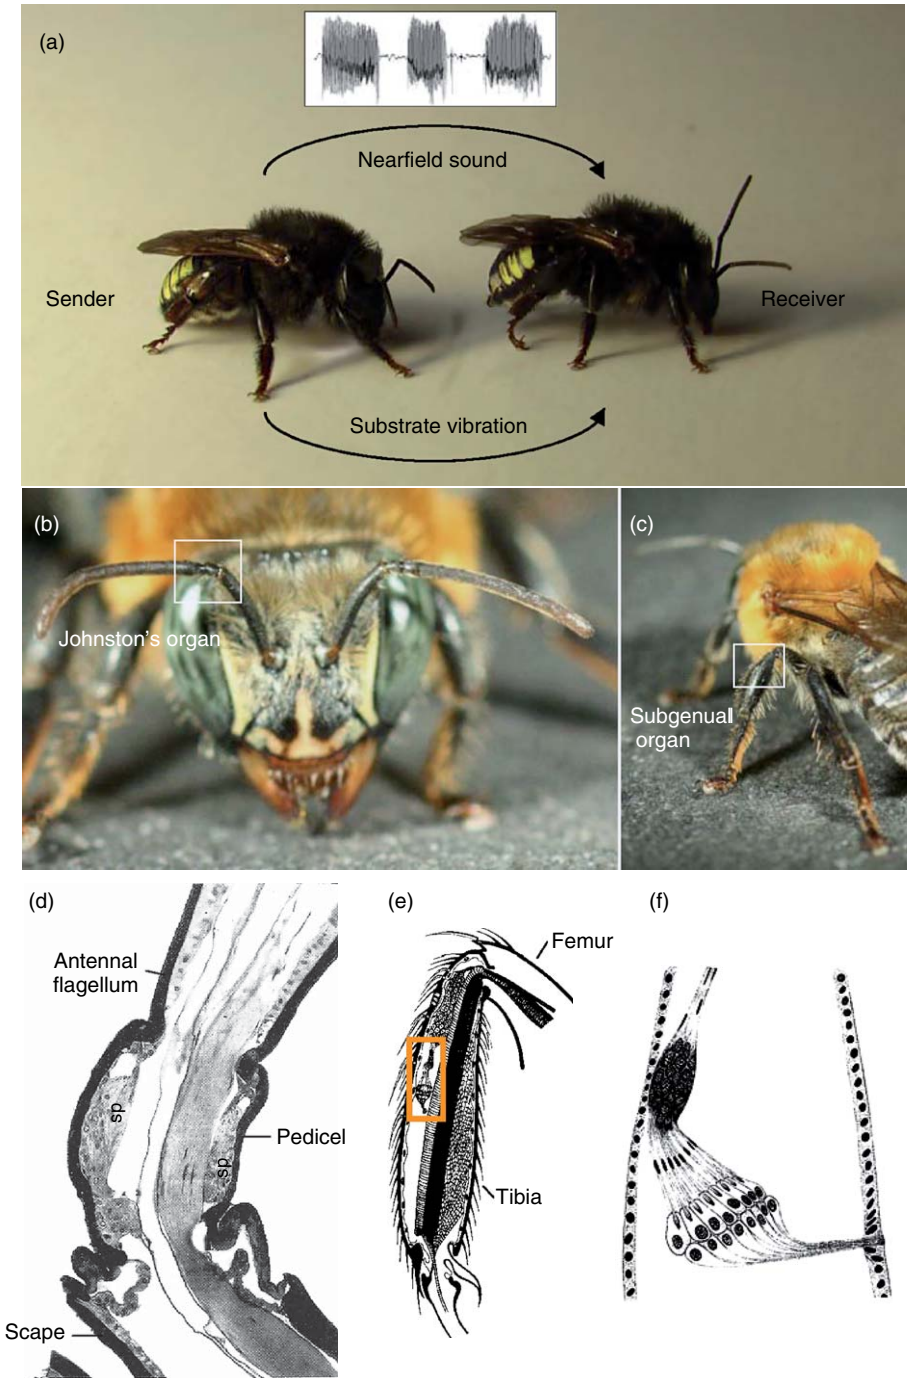

Figure 7 Acoustic communication in bees. (a) Schematic diagram depicting two possible communication channels between two honeybees: nearfield airborne sounds or substrate vibrations. (b) Airborne sounds induce vibrations of the antennal flagellum and stimulate sensory cells of the Johnston's organ. (c) The subgenual organ responds to axial vibrations of the tibia. The position of the leg (tibia) is important during signal reception. (d) Section of the antennal flagellum and pedicel of the honeybee antenna showing Johnston's organ. (e) Drawing of the subgenual organ of the leg of a honeybee. Boxed region is expanded in (f). (a–c) Photographs by M. Hrncir. (d) Reproduced from Dreller, C. and Kirchner, W. H. (1995) The sense of hearing in honey bees. Bee World 76(1), 6–17. (e, f) Reproduced from Schön, A. 1911. Bau und Entwicklung des tibialen Chordotonalorgans bei der Honigbiene und bei Ameisen. Zool. Jb. Anat. 31, 439–472, with permission from Elsevier Science Publishers Ltd.

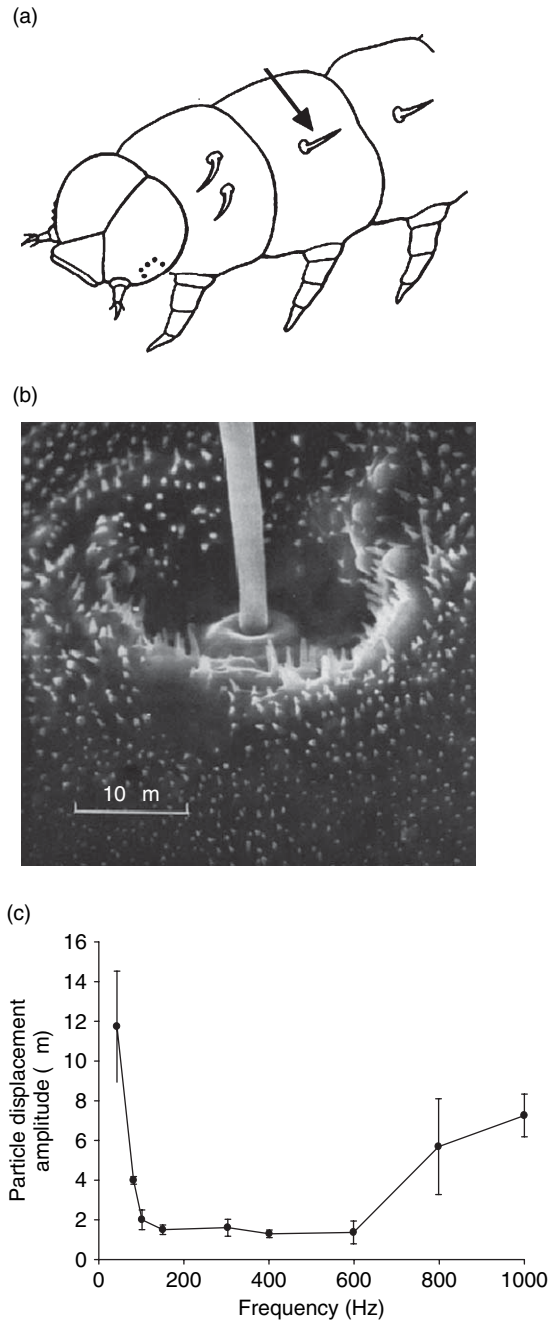

Figure 8 Nearfield sound receptors in a cabbage moth caterpillar *Barathra*. (a) The anterior end of the caterpillar, showing four thoracic trichoid sensilla. (b) A scanning electron micrograph of the base of a single trichoid sensillum. (c) Tuning curve of a single trichoid sensillum, which responds to the air particle displacements produced by the flight sounds of a parasitoid wasp, *Dolichovespula* sp. that lays eggs on the caterpillar. Adapted from Markl, H. and Tautz, J. 1975. The sensitivity of hair receptors in caterpillars of *Barathra brassicae* L. (Lepidoptera, Noctuidae) to particle movement in a sound field. J. Comp. Physiol. 99, 79–87.

few developmental steps to make a new ear from a preexisting proprioceptor. Some insects may rely on multiple tympanal ears, and a combination of sound and vibration receptors to form a perceptual construct of their environment. It is difficult for us to imagine a sensory world dominated by sounds and vibrations, which is probably the case for many insects.

Tympanal ears are structurally most similar to vertebrate ears in that they consist of an eardrum associated with sensory neurons that respond to far-field sounds (pressure waves). Unlike vertebrate ears, however, insect tympanal ears can occur on almost any part of the body (including the neck, wings, and mouth) and range in complexity from having a single auditory sense cell (in some moths) to over 2000 (in some grasshoppers and cicadas). Despite their small size, insect auditory systems are capable of performing complex tasks such as precise sound localization, frequency discrimination, pattern recognition, and categorical perception, similar to what we see in vertebrate auditory systems.

Much progress has been made in understanding insect auditory systems over the past few decades, thanks to developments in neural and vibrational recording techniques. Still, there are many puzzles, and exciting new avenues of research to explore in the field of insect sound and vibrational communication. First, we are still discovering new hearing organs. Recently it has been learnt that some insects possess highly sensitive hearing, but do not possess morphologically conspicuous hearing organs (i.e., they lack an obvious eardrum). It is very likely that hearing organs will be discovered in those insect groups that have been considered 'deaf', including the Hymenoptera (bees and wasps), and Odonates (dragonflies and damselflies). Second, despite our extensive knowledge of the structure of tympanal chordotonal organs, it's still not understood how these complex structures convert mechanical vibrations into nerve impulses. Developments in this area of study involving genetically manipulated auditory chordotonal organs, and insights into the molecular basis of mechanosensory channels, promise to shed light on this conundrum. Third, how acoustic signals are integrated at the level of the central nervous system to produce adaptive behaviors such as evasive flight, positive phonotaxis, or mate choice is an ongoing and exciting area of research. Finally, there is still much to learn about how insects detect and use solid-borne vibrations and nearfield sounds, and future explorations into these sensory modalities are sure to yield exciting new insights into the unique auditory sensory world of insects.

Glossary

azimuth Direction along the horizon relative to a listener.

functional head size The time it takes for sound to travel around the head from one ear to the other.

octave An interval between two frequencies that have a 2 to 1 ratio (0.25–0.5 kHz and 50–100 kHz are both intervals of one octave).

subterranean animals Animals that live their entire lives below ground.

Δt Difference in the time of arrival of a sound at the two ears.

Δfi Difference in the frequency–intensity spectra of a sound at the two ears.

3.03.1 Introduction

The first systematic study of high-frequency hearing was conducted by Francis Galton in the second half of the nineteenth century. Using a high-frequency whistle attached to his cane and operated by a rubber bulb, Galton observed the unconditioned responses of animals, including those of the London Zoological Gardens, to high-frequency sounds. His observations, which he briefly summarized in his book *Inquiries in Hhuman Faculty and Its Development* (1883), indicate that he found significant species differences in the ability to hear high frequencies or, as he referred to them, "shrill sounds." Of the animals he observed, he found cats to have the best high-frequency hearing, an ability he attributed to their need to hear the high-frequency sounds made by mice and the other small animals they catch. He also found small dogs to have good high-frequency hearing, although he believed that large dogs did not, as he was never able to get them to respond to his whistle. Thus, by the late nineteenth century, it was apparent that mammals vary in their ability to hear high-frequency sounds.

The purpose of this chapter is to explain both why mammals have good high-frequency hearing and why they differ in this ability. The explanation we offer does not address how mammals hear high frequencies, but why they do – mammals evolved high-frequency hearing for the purpose of localizing sound. Thus, the following is a description of the evolutionary pressures that have led to high-frequency hearing in mammals, rather than the mechanisms that underlie this ability.

Before beginning, some preliminary information will be useful. First, most nonmammalian vertebrates do not hear significantly above 10 kHz: birds have an upper limit of 8–12 kHz (Dooling, R. J. *et al.*, 2000) while reptiles, amphibians, and most fish do not hear above 5 kHz (Heffner, H. E. and Heffner, R. S., 1998; for an example of fish that hear high frequencies, see Mann, D.A. *et al.*, 2001). Thus, the almost universal ability of mammals to hear frequencies above 10 kHz

is a distinctly mammalian trait among vertebrates. Second, the term ultrasonic refers to frequencies above the nominal upper limit of humans, which is 20 kHz, and is therefore an anthropocentric term. A more appropriate perspective would be gained if we focus on the distinction between mammals and other vertebrates and consider any hearing above 10 kHz to be noteworthy. Finally, it should be noted that sound is perceived on a log scale, which in music is stated in octaves. Thus, although the difference between an upper limit of 50 and 100 kHz may seem greater than that between 5 and 10 kHz, both are differences of just one octave.

3.03.2 High-Frequency Hearing and Sound Localization

Although it was known that some mammals had better high-frequency hearing than others, it was not until 1967 that the discovery of systematic variation in mammalian high-frequency hearing was made by the late R. Bruce Masterton. In the course of determining the hearing abilities of several species of mammals, in preparation for a study of the auditory cortex, he noticed that smaller mammals had better high-frequency hearing than larger ones. Because he was studying sound localization at the time, he realized that this observation had implications for the use of the binaural locus cues: the difference in the time of arrival of a sound at the two ears (which he referred to as Δt), and the difference in the frequency–intensity spectra of the sound reaching the two ears (Δfi). Noting that the magnitude of the binaural time-difference cue depends on the size of an animal's head, he suggested that the smaller an animal's head, the more dependent it would be on the binaural spectral-difference cue (Masterton, B. *et al.*, 1969). However, to use the binaural spectral-difference cue, animals must hear frequencies high enough to be attenuated by their head and pinnae (thus generating intensity differences between the two ears) because small heads do not block low frequencies as effectively as they block higher ones. Therefore, the smaller an animal's functional head size (defined as the time it takes for sound to travel around the head from one ear to the other), the higher the frequencies it must hear to use the binaural spectral-difference cue for sound localization.

The relation between functional head size and high-frequency hearing has remained robust since its discovery ($r = -0.79$, $p < 0.0001$) and has been shown to hold for over 60 species ranging in size from mice and bats to humans and elephants (Figure 1). However, two points should be noted about this relationship. First, as can be seen in Figure 1, it does not apply to subterranean mammals; they are an exception that we shall later see proves the rule. Second, the relationship applies only to comparisons between species, not within species. For example, although dogs differ in head size by a factor of 2 (from Chihuahuas to St. Bernards), what little individual variation they show in high-frequency hearing is not related to their functional head size (Heffner, H. E., 1983). Thus, Galton, F. (1883) was wrong on one point – large dogs do have good high-frequency hearing. The failure of large dogs to respond to Galton's whistle demonstrates the weakness of using unconditioned responses for testing sensitivity and also suggests that large dogs may be unconcerned by objects that make only high-frequency sounds because such objects (usually other animals) are generally small.

3.03.2.1 Binaural Spectral-Difference Cue

The importance of high-frequency hearing for localizing sound in the horizontal (azimuthal) plane can be demonstrated by determining the ability of an animal to localize a broadband signal (i.e., noise) from which high frequencies are removed. Filtering out high frequencies has been shown to degrade azimuthal localization in monkeys, humans, chinchillas, and mice (Brown, C. H. *et al.*, 1982; Butler, R. A., 1986; Heffner, R. S. *et al.*, 1996; 2001a). Because the binaural time-difference cue is available in the low-frequency component of the signal, a decline in performance may be attributed to the absence of high frequencies necessary for using the binaural spectral-difference cue (assuming the use of pinna cues has been ruled out).

Although there is little doubt that the use of binaural spectral differences requires mammals to hear high frequencies, it is only part of the reason that mammals evolved high-frequency hearing. This point was dramatically demonstrated by the discovery that some mammals lack the ability to use the binaural spectral-difference cue but still hear high frequencies. Briefly, the ability to use the two binaural cues can be assessed by determining the ability of an animal to localize pure tones. Use of the binaural time-difference cue is indicated by the ability to localize low-frequency tones that pass around the head with little or no intensity difference between the ears. The ability to localize tones that are too high in frequency to permit the use of the

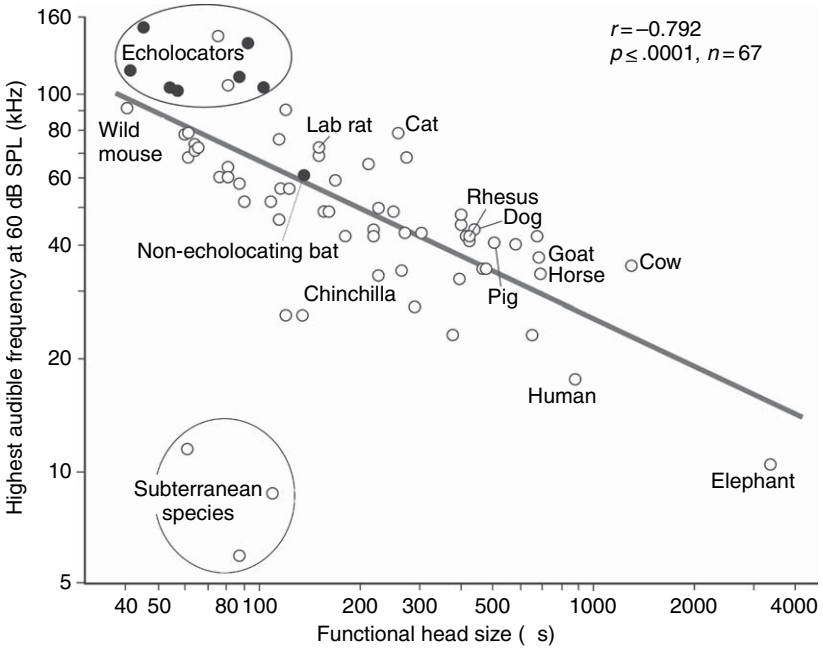

Figure 1 Relation between functional head size and high-frequency hearing (highest frequency audible at 60 dB sound pressure level) for mammals. This relationship is explained by the need of small mammals to hear higher frequencies than larger mammals in order to use the binaural spectral-difference cue and/or pinna cues to localize sound. Note that the subterranean species (naked mole-rat, blind mole-rat, and gopher), which do not localize sound, have lost the ability to hear high frequencies. Echolocating bats hear slightly higher than predicted based on their functional head size. Filled circles indicate bats, open circles indicate all other mammals. (The open circles among the echolocators are two species of cetacea.) For references to individual audiograms, see Koay G. *et al.* (1998a) and Heffner R. S. *et al.* (2003).

binaural time cue indicates that an animal can use the binaural spectral-difference cue (e.g., Heffner, R. S. *et al.*, 2001b; Heffner, H. E. and Heffner, R. S., 2003). The results of this test indicate that most mammals use both binaural cues (as, e.g., do humans, monkeys, and cats). Yet, some species do not use binaural time differences (such as hedgehogs, mice, laboratory rats, and some bats), and others are either partially or completely unable to use binaural spectral differences (Heffner, H. E. and Heffner, R. S., 2003). Specifically, Indian elephants and domestic goats are unable to localize pure tones in the upper end of their hearing range indicating that they do not use the spectral information in their highest audible frequencies to localize sound (Heffner, R. S. and Heffner, H. E., 1982; Heffner, H. E. and Heffner, R. S., 2003). Domestic pigs, horses, and cattle are more extreme in that they cannot localize high-frequency tones at all, leading to the conclusion that they have completely relinquished the ability to use the binaural spectral-difference cue (Heffner, R. S. and Heffner, H. E., 1986; 1989; Heffner, H. E. and Heffner, R. S., 2003). To explain the existence of good high-frequency hearing in animals that do not use the binaural spectral-difference cue, we turned to the third type of sound-localization cue which is produced by the external ear, namely the pinna cues.

3.03.2.2 Pinna Localization Cues

Although the role of the pinna in sound localization was demonstrated during the late nineteenth century, most twentieth century studies focused on the binaural locus cues (Butler, R. A., 1975). This resulted in the use of headphones for presenting stimuli thereby eliminating the pinnae, making it easy to lose sight of their importance. Over the years, the work of Robert Butler and others has demonstrated that the directionality of the pinna not only provides the primary cues for vertical localization and for preventing front–back confusions, but also provides effective cues for localizing sound in the horizontal plane (e.g., Butler, R. A., 1975; Musicant, A. D. and Butler, R. A., 1985). Indeed, as noted by Butler R. A. (1999), "We live in a world where many sounds emanating from the side are not sufficiently intense to stimulate the opposite ear," in which case a binaural comparison only indicates that

the sound source is somewhere within the hemifield of the ear receiving the sound and, in the absence of pinna cues, may result in the perception of the sound being located within the ear itself. Thus, there are situations in which the pinnae provide the only locus cues as to the horizontal and vertical location of a sound source within a hemifield. For pinna cues to be effective in humans, the sounds must contain frequencies above 4 kHz and even sounds as high as 15 kHz have been shown to be necessary for optimal localization performance. Thus, the upper two octaves of human hearing (from 4 to 16 kHz) appear to be used primarily, if not exclusively, for sound localization, as they are not necessary for the perception of speech.

Other mammals also require high frequencies for localizing in the vertical plane, as well as for preventing front–back confusions. For example, filtering out high frequencies from a broadband noise signal degrades sound-localization performance for front–back and vertical localization in chinchillas and for vertical localization in monkeys (Brown, C. H. *et al.*, 1982; Heffner, R. S. *et al.*, 1996). Horses, which lack the ability to use the binaural spectral-difference cue, still require high frequencies to use pinna cues for front–back localization (Heffner, H. E. and Heffner, R. S. 1983). Thus, although most mammals use their high-frequency hearing to obtain both binaural spectral differences and pinna cues, some, such as horses, pigs and cattle, use it only for pinna locus cues. In addition, it is likely that there are species that use their high-frequency hearing to obtain the binaural spectral-difference cue, but do not use pinna cues (such as cetacea and the pinnipeds that lack pinnae).

3.03.2.3 Subterranean Mammals

As previously noted, subterranean mammals do not have good high-frequency hearing and their upper limit of hearing does not fit the relation between functional head size and high-frequency hearing (Figure 1). However, the existence of these animals does not weaken the theory that mammals evolved good high-frequency hearing for sound localization, but, instead, strengthens it. This is because not only do the pocket gopher, naked mole-rat, and blind mole-rat lack good high-frequency hearing, they also lack the ability to localize sound (Heffner, R. S. and Heffner, H. E., 1990; 1992a; 1993). Thus, it appears that subterranean animals that are adapted to the one-dimensional world of an underground habitat have little use for sound localization and are therefore released from the selective pressure to hear high frequencies. In short, sound localization and high-frequency hearing go hand-in-hand in mammals. Mammals cannot optimally localize sound without high frequencies, and those that relinquish the ability to localize sound also give up their high frequency hearing.

3.03.2.4 Bats

Although bats require good high-frequency hearing for passive sound localization (Koay, G. *et al.*, 1998b), the question arises as to whether selective pressure for echolocation has caused bats to increase their high-frequency hearing beyond that required for passive sound localization. This possibility was recently examined by comparing the high-frequency hearing limits of bats with those of other mammals. The results of this comparison indicated that echolocating bats hear on average about 0.5 octaves higher than expected from their functional head size. Thus, although echolocating bats appear to owe 3.3 octaves of their high-frequency hearing to selective pressure for passive sound localization, they seem to have added an average of half an octave to their hearing ranges for use in echolocalization. In contrast, nonecholocating bats have not extended their high-frequency hearing beyond that expected for passive sound localization (Heffner, R. S. *et al.*, 2003).

3.03.2.5 Ultrasonic Communication

It is not unusual for small rodents to produce vocalizations that are above the range of human hearing, that is, ultrasonic (e.g., Nyby, J. and Whitney, G., 1978), and it has been suggested that high-frequency hearing evolved in order for animals to communicate via ultrasound (e.g., Sales, G. D. and Pye, J. D., 1974). Indeed, it would seem advantageous for small animals to use high-frequency communication signals because they are more directional and attenuate more rapidly over distance than low frequencies making them less likely to be detected by predators (Wilson, D. R. and Hare, F., 2004). However, whether such calls are inaudible to a predator depends on the predator's proximity as well as its auditory sensitivity.

Although the use of high-frequency communication signals by small mammals is well established, we have argued elsewhere that it appears to be a co-option of high-frequency hearing that originally evolved for sound localization (Heffner, H. E. and Heffner, R. S., 1985; Heffner, R. S., and Heffner, H. E.,

1985). One reason is that a species' upper limit of hearing often extends beyond that required for hearing its communication vocalizations, as in the case of cattle, dogs, and humans, which hear frequencies well above the dominant frequencies of their vocalizations. Another is that there is no clear sign that high-frequency communication has affected a species' auditory sensitivity. Although some species vocalize at frequencies corresponding to secondary peaks of sensitivity toward the midrange of their audiograms, these secondary peaks have been shown to result from the directionality of the pinnae and serve to enable animals to localize in the vertical plane (Koay, G. *et al*., 1998b). Finally, the fact that small animals produce high-frequency vocalizations is not surprising as it would require special adaptation for them to produce low-frequency calls as is the case for frogs and toads that use specialized vocal sacs to produce low-frequency call (e.g., Bradbury, J. W. and Vehrencamp, S. L., 1998).

3.03.3 Conclusion

The primary source of selective pressure for mammalian high-frequency hearing appears to be its role in localizing sound through use of the binaural spectral-difference cue, pinna cues, or both. Most mammals hear higher frequencies than humans because they have functionally smaller heads and therefore require higher frequencies to localize sound – when compared to the elephant, which only hears up to about 10 kHz, even humans have 'ultrasonic' hearing.

Finally, it may be noted that the understanding of high-frequency hearing is only one example of the insight that can be gained from a comparative analysis of hearing; other examples include low-frequency hearing (Heffner, R. S. and Heffner, H. E., 2001) and sound localization (Heffner, R. S., and Heffner, H. E., 1992b; Heffner, H. E. and Heffner, R. S., 2003). Indeed, the view that mammals evolved high-frequency hearing for sound localization suggests that nonmammals, such as birds, which lack high-frequency hearing, either do not localize sound as well as mammals (especially off to the side and in the vertical plane where pinna cues predominate) or else have evolved alternative mechanisms for sound localization, such as the facial ruff of the barn owl (Knudsen, E. I. and Konishi, M., 1979).

Glossary

audiogram A graphical representation of the sound amplitude threshold of hearing for a range of frequencies.

azimuth Angle in relation to the longitudinal axis of the body in the horizontal plane.

binaural Involving two ears.

clade A group of organisms that share a common ancestor. The group includes the ancestor and all its descendants.

cochlea The structure in the inner ear of reptiles, birds, and mammals that contains the sound sensitive sensory epithelium. In mammals only, the structure is coiled.

columella See stapes.

echolocation The use of acoustic reflections to infer the direction and distance of objects.

Eustachian tube A tube that links the middle ear to the pharynx and allows the passage of air, thus equalizing pressure across the tympanic membrane.

extracolumella See extrastapes.

extrastapes A cartilaginous element in the middle ear that connects the tympanic membrane to the stapes. Also known as the extracolumella.

fossorial Subterranean, living underground.

hair cells Auditory and vestibular transducers. Each possesses a stereovillar (hair) bundle protruding from its apical surface. The cell is sensitive to displacement of the hair bundle.

incus A bone in the mammalian middle ear that connects the malleus to the stapes. Also known as the anvil.

inferior colliculus The principal midbrain nucleus of the auditory pathway. It receives input from the peripheral auditory pathway, and from the auditory cortex.

interaural Between the two ears.

malleus A bone in the middle ear of mammals that connects the tympanic membrane to the incus. Also known as the hammer.

operculum Middle ear ossicle of amphibians that contacts the oval window and receives the insertion of muscles that attach to the scapula.

ostariophysan fishes Those belonging to the superorder *Ostariophysi* having four of the anterior vertebras modified for connecting the swim bladder to the inner ear (Weberian apparatus).

otolith A mineral concretion which makes contact with the hair bundles of several mechanoreceptive hair cells.
oval window A membrane-covered opening that separates the air-filled middle ear from the fluid-filled inner ear. It allows the middle ear ossicles to transmit vibrations from the tympanic membrane to the inner ear.
pinna The external ear.
spectral Relative to frequency.
stapes A bone in the middle ear that transmits vibrations to the oval window, and thus into the inner ear. Also known as the columella (in non-mammals) or stirrup.
swim bladder A gas-filled chamber with variable volume that allows fishes to control buoyancy. It can also have a role in hearing and sound production in some fishes.
tympanic membrane A thin membrane that senses airborne sound in the ears of vertebrates and separates the middle ear from the external environment. Also known as the eardrum.
ultrasound Sound with frequency above 20 kHz, which is about the nominal upper limit of human hearing.
weberian apparatus A set of bones that physically connect the swim bladder to the inner ears in order to enhance hearing.

3.04.1 Introduction

Most natural events involving physical movement produce some sound. The physical properties of the sound produced are correlated with properties of the body in motion and to properties of the movement. Vertebrates can detect many such sounds and may respond to them with adaptive behavior.

Hearing is unique among the senses in the combination of its functional attributes. It allows animals to respond to signals produced by remote sources. Sound is transmitted in the medium more quickly than odor and more slowly than light. Hearing is less affected than vision when an opaque object is present between the animal and the source of the stimulus. Hearing allows vertebrates to respond to vibrations in the air, underwater, and in the substrate (Fritzsch, B., 1992; Lewis, E. R. *et al.*, 2006). A close examination of vertebrate auditory systems frequently reveals specializations that match the acoustic environment that the animals inhabit or the structure of signals that are relevant to them (Numella, S. *et al.*, 2004; Pollak, G. D. and Casseday, J. H., 1989).

In this chapter, we focus on the ecological aspects of hearing in vertebrates. We review the structure and function of the auditory system in the main vertebrate clades and compare their performance. We also examine the current evidence on how habitat differences can affect vertebrate hearing. We intentionally omit a detailed discussion of auditory organization and processing in the central nervous system (for a review, see Carr, C. E., 1992; Grothe, B. *et al.*, 2004), but rather will focus on sound detection by the vertebrate peripheral auditory system.

More specifically, we compare threshold and frequency range across vertebrates. Next we examine auditory systems that transitioned between environments during evolution, as well as some of the effects of size and temperature on sound perception. We also review mechanisms of sound localization, an important capability for the detection of predators, prey, and potential mates. Finally, we present some examples illustrating the effects of noise derived from human activity on wildlife.

3.04.2 Auditory Structure and Function in Vertebrates

3.04.2.1 Otolith Organs

Vertebrates detect acoustic vibrations by sensing the relative motion between two parts of their body. A simple sensor has one element being moved by the sound and another element that remains stationary. In the underwater environment, this is complicated by the fact that most animal tissues are composed predominately of water and are transparent to sound. The problem is solved by adding a mineral concretion to the detector: the higher density of the mineral concretion results in a higher acoustic impedance than the surrounding tissues. When acoustic vibrations activate the sensor, the dense concretion lags behind the surrounding tissues, producing relative motion within the sensor.

The inner ears of fishes contain several otolith organs which can detect sound (Platt, C. and Popper, A. N., 1981; Popper, A. N. *et al.*, 2005; Figure 1). Each organ contains a mineral concretion called the otolith, which

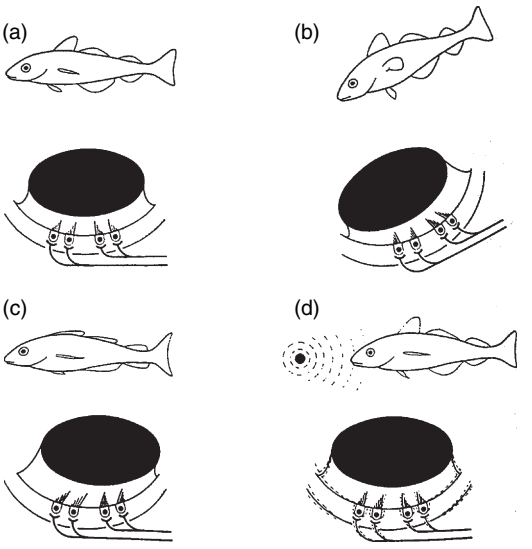

Figure 1 Schematic representation of an otolith organ showing the otolith in black and four hair cells under it. (a) The fish is static and horizontal; (b) The fish is static with the head down; (c) the fish is accelerating; (d) the fish is static, and detecting a sound that causes the otolith to vibrate over the hair cells. Reproduced from Behaviour of Telcost Fishes, 2nd, 1993, pp. 129–169, Underwater Sound and Fish Behaviour, Hawkins, A. D., figure 15.5, © Chapman and Hall, with kind permission of Springer Science and Business Media.

makes contact with a group of mechanoreceptive hair cells. The apical surface of each hair cell contains a hair (stereovillar) bundle, which is deflected when the otolith moves relative to the hair cell body. The patterns of neural output of the otolith organ depend on which hair cells are excited by the otolith and how the stereovillar bundle is deflected. Otolith organs respond to acceleration, which is produced in large part by gravity and by movements of the animal. Otolith organs allow fishes to sense the position of the head in relation to vertical and provide feedback to their movements. Position sensing is a general requirement in vertebrates and it was, most likely, the original function of the otolith organs (see articles in Manley, G. A. *et al.*, 2004).

Fishes do not have middle or external ears. As mentioned before, the flesh of the animal is composed mostly by water and it is transparent to sound. The inner ears can be very sensitive without being connected directly to the external world.

3.04.2.2 The Swim Bladder

Besides using the high density of the otolith to detect sound, many teleost fishes also take advantage of the very low density of the gas in their swim bladder (Ladich, F. and Bass, A. H., 2003). Sound pressure waves arriving at the animal produce larger volume changes in the swim bladder than in the flesh. It is thought that the swim bladder itself reradiates sound which is then detected by the ear. Experiments in which the gas was artificially removed from the swim bladder revealed a reduction in hearing sensitivity at high frequencies, whereas when a small air-filled balloon was placed under the head of the fish, hearing sensitivity increased (Sand, O. and Enger, P. S., 1973; Chapman, C. J. and Sand, O., 1974; Fay, R. R. and Popper, A. N., 1975). In the ostariophysan teleosts, the swim bladder is physically connected to the inner ears, via a series of four bones known as the Weberian apparatus: scaphium, claustrum, tripus, and intercalarium. This arrangement permits the direct transmission of swim bladder vibrations to the otolith organs, thus increasing the acoustic sensitivity of the fish (Hawkins, A. D., 1993). The Weberian apparatus is derived from vertebral elements that are not homologus to mammalian middle ear ossicles. This apparatus is analogous to the middle ear for transmitting sound pressure information to the inner ear.

3.04.2.3 Middle Ears

In the terrestrial environment, animals can detect acoustic vibrations arriving to them through the air or the substrate. The first terrestrial vertebrates lacked middle ears and probably preferentially perceived substrate vibrations over airborne vibrations (Clack, J. A., 1992; Clack, J. A. and Allin, E., 2004). Since air is much less dense and more elastic than water or flesh, a large acoustic impedance mismatch occurred between the skin of the animal and the air surrounding it. Most of the acoustic energy reaching the skin of the animal was reflected and did not reach the inner ear. Since soil is more similar in density and elasticity to animal tissues than is air, vibrations arriving from the soil could be coupled more efficiently to the tissues and would more likely be detected by the inner ear.

The evolution of the middle ear helped to resolve the acoustic impedance mismatch between animal tissues and air, greatly improving the airborne sound detection capabilities of terrestrial vertebrates. This occurred independently in the major clades (Clack, J. A. and Allin, E., 2004). Terrestrial animals evolved a tympanic membrane in contact with the external air (Figure 2). The thinness of the membrane and the presence of an air-filled cavity behind it reduces the impedance mismatch with the air and allows it to

E., figure 21.2, © Springer-Verlag, with kind permission of Springer Science and Business Media.

follow airborne pressure fluctuations within a range of frequencies. Vibrations of the tympanic membrane are conducted to the inner ear by a cartilaginous-bony ossicle called the columella or stapes. In amphibians, the stapes crosses the tissues of the back of the air-filled otic cavity to reach the inner ear (Smotherman, M. and Narins, P. M., 2004). In amniotes (reptiles, birds, and mammals), the otic cavity extends to the inner ear (Rosowski, J. J., 1994). The large area of the tympanic membrane relative to the stapes footplate, and the lever action performed at the connections of the stapes, allows the middle ear to approximately match the impedance of the air at the tympanic membrane to the impedance of the inner ear at the stapes footplate (Jorgensen, M. B. and Kanneworff, M., 1998; Mason, M. J. and Narins, P. M., 2002a).

In North American bullfrogs (*Rana catesbeiana*), the bony proximal portion of the stapes is rigid, but its distal segment forms a flexible articulation with a cartilaginous element called the plectrum (Capranica, R. R., 1976) or extrastapes (Mason, M. J. and Narins, P. M., 2002a). This flexible articulation confers on the amphibian middle ear a distinct mammal-like quality which in some species may be responsible for their extended high-frequency range (Mason, M. J. and Narins, P. M., 2002a). The tympanic membrane is also connected to the extrastapes. When the tympanic membrane vibrates, the extrastapes rocks over its flexible ascending process that attaches to the skull, and pushes or pulls the distal end of the stapes. If the ascending process is severed, transfer of vibrations from the extrastapes to the stapes is greatly reduced (Mason, M. J. and Narins, P. M., 2002a).

The stapes footplate contacts the inner ear at the oval window. In anuran amphibians, the oval window contains both the stapes footplate and a second bone called the operculum. The latter receives an insertion of the opercularis muscle, which connects it to the scapula, in the shoulder girdle (Figure 3). The opercularis system has been implicated both in the perception of vibrations from the substrate (Paton, J., 1971; Hetherington, T. E., 1985) and in the improvement of tympanic hearing by compensation for breathing (Mason, M. J. and Narins, P. M., 2002b).

In mammals, the evolution of a new jaw articulation point allowed the middle ear to incorporate two extra ossicles, the malleus and the incus (Rosowski, J. J., 1994; Clack, J. A. and Allin, E., 2004; Figure 4). Vibrations of the tympanic membrane are transmitted to the oval window by an articulated chain of three ossicles, as opposed to birds and reptiles, which transmit vibrations with a single ossicle, the stapes.

The extended high-frequency sensitivity of mammals relative to other vertebrates has been attributed to the incorporation of the tri-ossicular middle ear, consisting of an articulated structure composed of

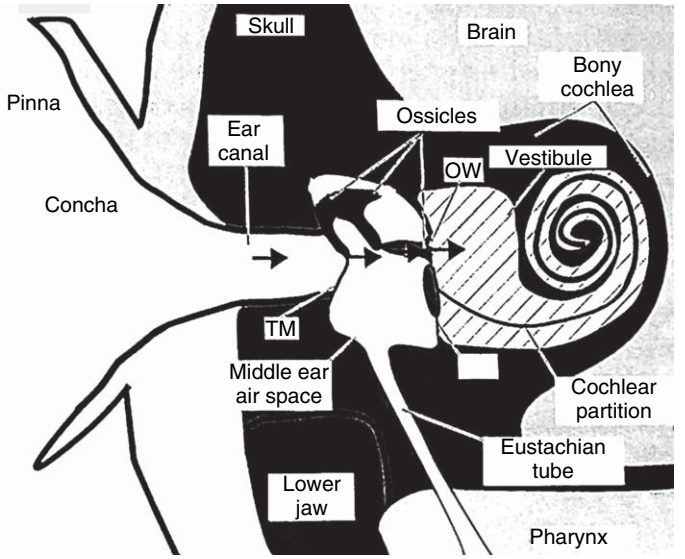

Figure 4 Schematic posterior view of the mammalian ear. OW, oval window; TM, tympanic membrane. Reproduced from Comparative Hearing: Mammals, 1994, pp. 172–248, Outer and Middle Ears, Rosowski, J. J., figure 6.2, © Springer-Verlag, with kind permission of Springer Science and Business Media.

three rigid elements. Moreover, in amphibians such as *Rana catesbeiana*, which rely on a single middle ear ossicle to transmit vibrations from the tympanic membrane to the inner ear, the articulation with the tympanum is cartilaginous and could potentially absorb high frequencies. In contrast, recent studies have recorded single-unit responses from the inferior colliculus (torus semicircularis) of the relatively small, arboreal frog *Amolops tormotus* at frequencies above 25 kHz (Feng, A. S. *et al.*, 2006). This species exploits a recessed tympanic membrane connected to low-mass ossicular elements, with a nonarticulated connection with the tympanum (personal observations). This calls into question the idea that a mono-ossicular middle ear is the main factor limiting the upper frequency range in nonmammalian vertebrates (see Mason, M. J. and Narins, P. M., 2002a).

3.04.2.4 Sensory Epithelia

The sensory organs in the inner ears of vertebrates vary in number, size, shape, and orientation of hair cell bundles (Lewis, E. R. *et al.*, 1985; Coffin, A. *et al.*, 2004). They also vary in number and types of hair cells that they contain and thus the homology among some vertebrate inner ear sensory organs is uncertain. The hearing organs of teleost fishes contain an otolith composed mainly of calcium carbonate and protein (Platt, C. and Popper, A. N., 1981; Hawkins, A. D., 1993; Popper, A. N. *et al.*, 2005). In elasmobranchs and other vertebrates, the otolithic structure is composed of a gelatinous mass containing calcium carbonate crystals, called otoconia.

Hair cells vary in their response to sound frequency (Fettiplace, R. and Fuchs, P. A., 1999; Smotherman, M. and Narins, P. M., 2000). In some inner ear organs such as the amphibian papilla of frogs and the cochlea in amniotes, hair cells are arranged by frequency sensitivity (tonotopic organization). These sensory organs tend to have an elongated structure (Miller, M. R., 1992; Figure 5), which reaches an extreme in birds and mammals (Manley, G. A. and Clack, J. A., 2004). In mammals other than monotremes, coiling of the cochlea not only allows for packing of an elongated epithelium in a small space but may also produce a low-frequency gain in sensitivity (Manoussaki, D. *et al.*, 2006). The epithelial length and the packing of the hair cells along the sensory epithelium are highly correlated both with the range of frequency sensitivity of the ear and its frequency resolution (Fay, R. R., 1992).

3.04.3 Hearing Performance in the Vertebrate Classes

Significant variation is found among and within behavioral audiograms of the five major classes of vertebrates (Fay, R. R., 1992; Figure 6). While most fishes cannot hear above 3 kHz, some species of the

order *Clupeiformes* have the capability of responding to ultrasound up to 180 kHz (Mann, D. A. *et al.*, 1997; Higgs, D. M., 2004). The mechanism and function of such capability is yet unknown, but its potential for use in avoidance of echolocating marine mammal predators is under investigation. Relatively few behavioral audiograms are available for amphibians and reptiles. Those that exist, together with neurophysiological recordings from anuran auditory nerve fibers, suggest a frequency range up to about 5 kHz (Feng, A. S. *et al.*, 1975; Wilczynski, W. and Capranica, R. R., 1984; Wilczynski, W. *et al.*, 1987; Narins, P. M. and Wagner, I., 1989; Wilczynski, W. *et al.*, 1992; 2001), with exceptions showing ultrasonic hearing (see below). Many birds can hear up to 8 kHz, this class being the most homogeneous among vertebrates. The extended hearing frequency range of birds has been ascribed to the elongation of the sensory epithelium in the cochlea (Manley, G. A. and Clack, J. A., 2004). Frequency range is further extended in mammals where it reaches above 100 kHz in cetaceans and bats. The lower limit of the frequency range in mammals is also variable; primates, elephants, and some rodents can perceive the lowest sound frequencies (Reuter, T. *et al.*, 1998; Webster, D. B. and Plassmann, W., 1992).

The lowest threshold of hearing is more variable within the classes than among the most sensitive or the average representatives of each class. The threshold of hearing is lowest in mammals, and lower in birds than in amphibians, reptiles, or fishes. Ostariophysan fishes have considerably lower hearing thresholds than nonostariophysans (see Section 3.04.2.2). Behavioral and neurophysiological recordings in amphibians have revealed lowest thresholds between 20 and 55 dB sound pressure level (SPL; Feng, A. S. *et al.*, 1975; Wilczynski, W. and Capranica, R. R., 1984, Wilczynski, W. *et al.*, 1987; Narins, P. M. and Wagner, I., 1989; Wilczynski, W. *et al.*, 1992; 2001). Eighth nerve recordings in geckos suggest lowest thresholds of about 20 dB SPL or lower (Manley, G. A., 1972; Dodd, F. and

Capranica, R. R., 1992; Werner, Y. L. and Wever, E. G., 1995) whereas lowest thresholds measured for snakes are about 40 dB SPL (Young, B., 2003).

The generalizations above should be taken with caution, as behavioral audiograms are only available for about 200 out of more than 50 000 species of vertebrates (Fay, R. R., 1992). Auditory specialists can often deviate significantly from the other members of their class, and can be instructive as a result. One example is the audiogram of the echolocating mustached bat (*Pteronotus parnellii*), with a very pronounced sensitivity peak at the dominant frequency of the echolocation calls (Figure 7). The sensitivity is not extreme, but the sharp peak in the audiogram clearly deviates from the common pattern for mammals, reflecting an adaptation to maximize reception of the echo (Pollak, G. D. and Casseday, J. H., 1989). Another apparent specialist is the concave-eared torrent frog, *Amolops tormotus*, which is a frog that lives in China near rushing streams that generate masking noise up to 20 kHz. It produces and detects calls at frequencies above those of the background noise (Narins, P. M. *et al.*, 2004; Feng, A. S. *et al.*, 2006). Ultrasonic communication might be an adaptation to the noisy environment, although other sympatric species such as the piebald odorous frog, *Odorrana schmackeri*, lack ultrasonic sensitivity (Yu, Z. L. *et al.*, 2006). Besides ultrasound, some frogs in similar noisy environments make use of visual signals for communication (Hödl, W. and Amézquita, A., 2001).

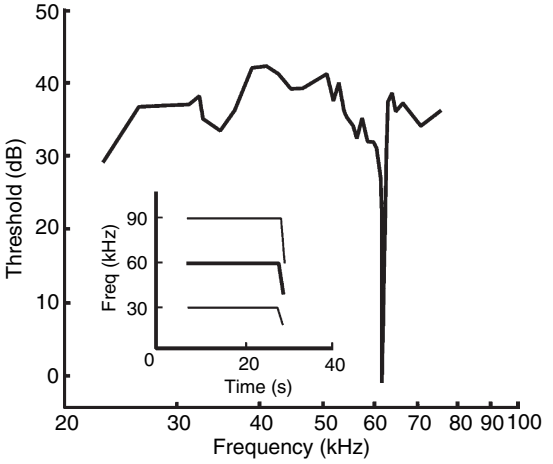

Figure 7 Cochlear microphonic audiogram of Parnell's mustached bat (*Pteronotus parnellii*). A schematic spectrogram of the echolocation call of the same species is inserted to show the close match between the dominant frequency of the call and the peak sensitivity of the ears. 3.04.4 Relations Between Hearing Structure and the Medium

Vertebrate ears frequently exhibit structural or mechanical adaptations to their acoustic environment. These are evident in diverse clades of animals with representatives living in contrasting environments.

Terrestrial rodent hearing is often characterized by high sensitivity and wide frequency range (Burda, H. *et al.*, 1992; Lange, S. *et al.*, 2004). Fossorial species usually show reduced high-frequency sensitivity and increased sensitivity at very low frequencies (Heffner, R. S. and Heffner, H. E., 1992b; 1993; Heffner, R. S. *et al.*, 1994). The reduced high-frequency sensitivity is likely related to the reduced availability of high-frequency sounds in the subterranean environment. Moreover, high-frequency sounds and sound filtering by the pinnae are important for sound localization by terrestrial animals. Fossorial species that lack pinnae spend much time in tunnels or burrows, where sound localization abilities are less essential. The low-frequency hearing of subterranean species, however, tends to be enhanced. Low frequencies are better transmitted by the soil and make up most of the acoustic input in the tunnels (Heth, G. *et al.*, 1986; Narins, P. M. *et al.*, 1992). Fossorial mammals in general exhibit middle ears with enlarged stapes footplates, reduced lever ratios and musculature, but similar tympanic membrane and ossicle sizes in relation to nonfossorial mammals (Burda, H. *et al.*, 1992; Mason, M. J., 2001). The reduced characters might relate to the loss of high-frequency sensitivity in fossorial mammals, but comparisons of the inner ears may reveal additional changes.

Snakes could, in principle, allow for an informative species comparison, having exemplars with auditory systems that operate in the terrestrial, aquatic, or fossorial environments (Young, B., 2003). The literature on snake hearing, however, is largely lacking, possibly because the species that have been studied revealed relatively limited frequency range and sensitivity (Wever, E. G. and Vernon, J. A., 1960; Wever, E. G., 1978).

The terrestrial–aquatic transition in cetaceans provides a fine example of adjustment of the hearing

apparatus to a change of medium. In terrestrial mammals, the impedance mismatch between air and tissues causes reflection of sound at the skin. Airborne sound, therefore, reaches the ear through the auditory meatus only (Figure 8).

When a terrestrial animal dives, the auditory meatus fills with water and reduces the efficacy of the tympanic membrane in transmitting sound. In addition, underwater sound can cross the head tissues and reach the ears from any direction, nullifying the effect of the head and external ears in sound localization. In odontocetes, the auditory meatus is nonfunctional and sound reaches the ears through a different path which is a large mandibular foramen that channels the sound through a fat pad that connects to the middle ear (Ketten, D. R., 2000). The ear is nearly acoustically isolated from the skull by a layer of air-filled sinuses. Such a system provides a novel path for sound to reach the inner ears and preserves directional cues. Intermediate stages in the specializations of the cetacean ear are observed in ontogeny (Kinkel, M. D. *et al.*, 2001) and in the fossil evidence, which documents gradual but rapid adaptation of the ears for effective hearing under water (Thewissen, J. G. M. and Hussain, S. T., 1993; Nummela, S. *et al.*, 2004).

3.04.5 Allometry

Allometric relations in vertebrate hearing have been best characterized at the macroscopic level. Studies of otolith size in fishes have found an association between the size of the fish, the size of the otolith, and frequency range (Cruz, A. and Lombarte, A., 2004; Popper, A. N. *et al.*, 2005). As the fish grows,

more hair cells are added to the sensory epithelium, potentially expanding the frequency range of hearing, although direct confirmation of this association is still lacking (Popper, A. N. *et al.*, 2005).

In birds and mammals, the dimensions of the cochlea and packing of the hair cells provide close estimates of the frequency range and resolution of the auditory system. The tonotopic organization of the cochlea makes it possible to map sound frequency to a particular region of the cochlea, generating frequency-position maps (von Békésy, G., 1960). With the assumption that the frequency bands correspond to equal distances on the basilar membrane independent of frequency, a frequency-position map can be derived in which sound frequency is calculated based on position in the cochlea, a slope term, and the frequency range of the cochlear map (Greenwood, D. D., 1961).

Empirical data indicate that the slope term is constant among species if cochlear length is normalized and the frequency range term is a simple proportion of the highest frequency audible at 60 dB SPL (Greenwood, D. D., 1990; Fay, R. R., 1992). The cochlear map can therefore be derived based on the length of the basilar membrane and the maximum audible frequency, and produce exceptional fits with empirical measurements for birds and mammals. Such maps also generate precise predictions of frequency analysis capabilities in mammals and birds (Fay, R. R., 1992).

Poor fit of the model with empirical data was encountered in hearing specialists such as the greater horseshoe bat (*Rhinolophus ferrumequinum*) which performs detailed frequency analysis over a narrow range to compensate for Doppler shifts of its echolocation calls. The critical cochlear distance is however, rather constant for most other mammals, and for most studied birds, but it is about 3.3 larger in mammals than in birds. The reduced variation in critical cochlear distance found within mammals and birds results in species with long basilar membranes and poor high-frequency hearing having the best frequency acuity (Fay, R. R., 1992). Comparison of the audiograms of living birds with basilar papilla sizes in birds and fossils of their ancestors allowed for inference of the hearing capabilities of several dinosaurs, and indicated that they should have been mostly sensitive to very low frequencies (Gleich, O. *et al.*, 2005).

In general, large structures have increased mass and inertia, which tunes the hearing organ to low frequencies (Hetherington, T. E., 1992). High-frequency specialists such as the frog *Amolops tormotus* have a middle ear of reduced size, whereas low-frequency specialists tend to have large middle-ear ossicles (Feng, A. S. *et al.*, 2006). Golden moles (*Chrysochloridae*) are an extreme example, having highly hypertrophied mallei. Besides hearing airborne sounds that are detected by the tympanic membrane, golden moles can sense low-frequency seismic vibrations (Narins, P. M. *et al.*, 1997). The large mass of the malleus and the displacement of its center of mass from the rotation axis of the bone renders this ossicle a highly sensitive inertial motion detector (Mason, M. J. and Narins, P. M., 2002c; Willi, U. B. *et al.*, 2006).

3.04.6 Physiology

Several physiological factors can affect hearing in ectothermic vertebrates, especially temperature. For example, frogs carry out most of their sexual communication in conditions in which variations of 10 °C are frequently experienced throughout the course of one night, and variations of 20 °C are common over the breeding season. In addition, these animals can experience significant reductions of body temperature when they enter the water.

At low temperatures, hearing sensitivity is reduced and in some species the range and the frequency of best sensitivity also drops (Walkowiak, W., 1980; Stiebler, I. and Narins, P .M., 1990; van Dijk, P. *et al.*, 1990). In the gray treefrog, *Hyla versicolor*, temperature affects the preference of females for the rate of acoustic pulses in the advertisement calls emitted by males (Gerhardt, H. C., 1978). This is relevant because temperature also affects the acoustic pulse rate of male calls. *H. versicolor* frequently co-occurs with its sister species, *H. chrysoscelis*, and pulse rate is the main difference in their advertisement calls. The variation of female preference for pulse rate in response to temperature compensates for the variation in male call rate with temperature. This allows male trait and female preference to fluctuate with temperature in both species while matching males and females within each species and maintaining species isolation. The mechanism that couples female preference for call rate to temperature in either species is unknown.

3.04.7 Localization

Localizing a sound source involves estimating azimuth (angle in relation to the longitudinal axis of the body in the horizontal plane), elevation, and distance to the

source. Much is known about sound localization in humans and basic processes seem to be generalizable to some other mammals (Fay, R. R. and Popper, A. N., 2005). Other classes of vertebrates exhibit important differences in peripheral and central organization of the auditory system, and appear to have evolved independent mechanisms of sound source localization (for recent reviews, see Christensen-Dalsgaard, J., 2005; Chapter Interconnections Between the Ears in Nonmammalian Vertebrates).

Terrestrial vertebrates localize sound sources by cuing on interaural differences in the acoustic signal (binaural cues). Localization by binaural cues presents a greater challenge underwater. Sound transmission is about four times faster in water than in air, significantly reducing the time of arrival difference of off-axis sound to the ears (Ketten, D. R., 2000). The wavelength of sound is also about four times longer under water, resulting in a vanishingly small interaural phase difference for low frequencies. Nevertheless, several cetaceans have been shown to echolocate and to localize sound as well as humans, with an acuity of about 1° (Heffner, R. S. and Heffner, H. E., 1992a).

Binaural cues in terrestrial vertebrates are also formed by the sound reflected by the head, resulting in a sound shadow in which sound at the distal ear is attenuated relative to that at the proximal ear. This effect is especially salient for $\lambda \leq d/10$, where $\lambda =$ wavelength of sound, and $d =$ diameter of the head (Yost, W. A., 2000). This effect is strongly diminished under water, both because animal tissues are mostly composed of water and are transparent to underwater sound, and because the wavelength of sound is longer in water than in air, for any given frequency. Fish heads do not produce, therefore, a significant sound shadow.

Nevertheless, experimental evidence indicates that fishes can localize sound sources (Hawkins, A. D., 1993; Myrberg, A. A., Jr., 2001; Fay, R. R., 2005). They can be conditioned to approach sound sources that they would normally avoid, and they can perceive a change of source position of at least 20° of separation in azimuth or elevation, as well as changes in distance to the sound source. They show directional responses in the near and far sound fields. Fishes possess three otolith organs (utricle, sacculus, and lagena) that detect particle motion. Direction of movement in such organs can be encoded by the motion of the otolith, producing displacement of the bundles of specific hair cells (Fay, R. R., 1984). In addition, these organs are positioned at different orientations and their combined output facilitates orientation in three dimensions. If the outputs from the hair cells are analyzed independently in the central nervous system, fishes should be capable of detecting the direction of the sound source (Lu, Z. *et al.*, 1998; Lu, Z. and Popper, A. A., 2001).

While the otolith organs might inform the fish about the azimuth of sound propagation, it is not clear how the direction is determined, that is, how the 180° ambiguity problem is solved. For instance, if the azimuth is perpendicular to the longitudinal axis of the body, the sound source might be located to the left or to the right. Experiments with cod (*Gadus morhua*) suggest that these fishes cue on the phase delay between sound pressure and particle motion to solve the 180° ambiguity (Hawkins, A. D., 1993; Wubbels, R. J. and Schellart, N. A. M., 1997). Since the swim bladder can act as a sound pressure detector, coupling of its motion to that of the otolith organs might allow the fish to identify the direction of the source. Further studies should corroborate such a mechanism and explain how nonostariophysan fishes including those that lack swim bladders can determine the direction of the sound source.

In terrestrial vertebrates, external sound is transmitted to the inner ear by the middle ear, which evolved independently in the four clades (Clack, J. A. and Allin, E., 2004). Treefrogs have been shown to be capable of resolving azimuth separations down to about 16°, or 9° after head scanning, and elevations of about 30° (Feng, A. S. *et al.*, 1976; Gerhardt, H. C. and Rheinlaender, J., 1982; Michelsen, A. *et al.*, 1986). Data on reptiles are very scarce, in part because of the difficulty of training them to respond to changes in sound direction (Christensen-Dalsgaard, J., 2005). The best studied example of precise localization ability in birds is the barn owl (*Tyto alba*), with an azimuthal and elevational acuity of approximately 5°, but extensive variability is found in birds, and acuities up to 25° have been described (Knudsen, E. L. and Konishi, M., 1979; Bala, A. D. S. *et al.*, 2003; Christensen-Dalsgaard, J., 2005). Mammals range in both azimuthal and elevational acuities of about 1° to more than 20° and the extensive variability makes it difficult to establish causal links to features of anatomy or lifestyle (Heffner, R. S. and Heffner, H. E., 1992a).

Elevation in terrestrial vertebrates is mostly determined by analysis of the spectral attributes of the perceived sound. The head and the pinnae modify sounds of different frequencies by various amounts, and this varies with sound elevation due to the shape

of the head and pinnae (Brown, C. H. and May, B. J., 2005). Each elevation has, therefore, a signature of relative amplitudes of frequencies to which the animal may cue.

One important structural factor in sound localization in terrestrial vertebrates is the connection between the ears. In mammals, the Eustachian tubes are generally closed and comparisons between the inputs of the two ears are performed by the central nervous system. These acoustically isolated ears are called pressure detectors. In amphibians, the Eustachian tubes remain mostly open and in reptiles and many birds, the ears are often coupled via interaural canals (Lewis, B. and Coles, B., 1980; Klump, G. M., 2000; Christensen-Dalsgaard, J. and Manley, G. A., 2005). One consequence of the direct connection between the ears is that each ear contributes to the response of the other. In particular, the driving force on one tympanic membrane is the sound pressure difference or gradient across it at any moment, rather than simply the external sound pressure impinging upon it (Narins, P. M., 1995; Christensen-Dalsgaard, J., 2005).

Limitations and performance of the ears differ between connected and nonconnected middle ears. When the sound arrives from an angle which results in a phase difference of 180° across the eardrum of a pressure-gradient detector ear, the amplitude of the signal is doubled in relation to pressure difference detectors. At very low frequencies, the phase difference between the ears might be too small and not produce sufficient stimulation for localization by pressure gradient detectors. At very high frequencies, the sound might arrive to the two ears with phase differences of more than 360° and produce an input subject to ambiguous interpretation. Pressure gradient detectors (connected ears) offer the advantages of peripheral processing of binaural difference and increased sensitivity at intermediate frequencies, at the cost of being functionally restricted to the intermediate frequencies. Several birds, especially high-frequency hearing specialists such as owls, experience an intermediate situation. They have thin and long Eustachian tubes that add impedance to the connection between the ears, rendering them intermediates between pressure and pressure-gradient detectors.

The connection between the ears is relevant for altering the range and sensitivity of the ears but it can also have evolutionary implications as the output of connected ears likely requires very different neural processing for localization than the output of acoustically isolated ears.

3.04.8 Management of the Acoustic Environment

With advancement of technology, we have witnessed the inevitable increase in the diversity and abundance of human-made noisy devices present in the environment. Concern has been raised about the potentially negative effects on wildlife caused by human-made sound sources. This has inspired several research initiatives addressing various taxonomic groups, environments, and experimental setups.

The effect of noise in aquatic environments has received extensive reviews (Richardson, W. J. *et al.*, 1997; National Research Council U.S., 2005). In terrestrial environments, loud noise produced by airplanes, helicopters, and chainsaws was shown to have temporary deleterious effects on birds and mammals (Luick, B. R. *et al.*, 1996; Conomy, J. T. *et al.*, 1998; Delaney, D. K. *et al.*, 1999). Several studies have found behavioral adjustments by animals to anthropogenic noise. Nightingales call at higher intensities in territories where the background noise is intense (Brum, H., 2004), and great tits (*Parus major*) increase the pitch of their calls in noisy environments (Slabekoorn, M. and Peet, M., 2003). When exposed to playback of white noise, white-lipped frogs (*Leptodactylus albilabris*) switch their attention from the acoustic component of neighboring male calls to the seismic component, which is produced by thumping of the vocal sac against the substrate (Lewis, E. R. *et al.*, 2001). Marmoset monkeys (*Callithrix jacchus*) respond to noise playbacks by increasing the intensity and the duration of their calls (Brum, H. *et al.*, 2004). Studies on tree swallows (*Tachycineta bicolor*) showed that chicks increased begging call amplitude when exposed to white noise, both in the field and in captivity (Leonard, M. and Horn, A. G., 2005). The natural preference of parents to high begging-call rate disappeared under elevated noise, but it was reestablished when the intensity of the begging calls was increased to match the intensities produced by the chicks when exposed to noise.

Adjustments to the calling patterns in response to noise by males within a vocalizing assemblage may differ among species. Sun J. W. C. and Narins P. M. (2005) studied the responses of multiple species of frogs to playbacks of anthropogenic noise at a pond in central Thailand. Species varied widely on how their

call rates were affected by the noise. While most species silenced to various degrees following the stimuli, one species, the Taipei Frog (*Rana taipehensis*), increased its call rate. Anthropogenic noise might alter, therefore, the natural dynamics of frog choruses, and the degree of masking to which each species is exposed.

Besides behavior, studies have also found evidence of evolutionary adjustment of species to local environmental noise (Witte, K. *et al*., 2005). Cricket frogs (*Acris crepitans*) in Texas inhabit both open areas and pine forests. Male calls from forest areas degrade less than male calls from open areas when broadcast from either of the two environments. The auditory nerve fiber tuning curves of females from forest areas are also more sharply tuned than those of females from open areas, and therefore may more effectively filter out cricket frog calls from the local environmental noise in both environments. These results suggest that the environmental acoustics of the forest habitat has selected for adaptations of both male calls and female auditory systems of local cricket frogs to efficiently function in a noisy environment.

Considering the diversity of auditory systems and life history strategies found in nature, generalizations from these types of studies should be made with caution. Research must continue to access more species, environments, and noise sources as the impact caused by human-kind increases. As an added benefit, investigations of the responses of wildlife to anthropogenic noise produce new information about the hearing and behavior of those species in question. Such studies can also identify modifications to the noise-making devices that reduce their negative impact on wildlife without significantly compromising functionality.

Glossary

autosomal dominant An effect caused by mutations in a single allele of a gene in the autosomal chromosomes.

cochlear amplifier A mechanism to enhance the perception of stimuli of low intensity.

coelenterates Radial symmetric animals (jellyfish, corals).

DEG/ENAC Degenerin/epithelial sodium channels, a family of ion channels.

ecdysozoans Animals that shed the external layer of skin through the action of the hormone ecdyson.

eukaryotes Single and multicellular organisms that have all DNA (except for mtDNA) concentrated in one or more nuclei.

kinocilium A nonmotile flagellum like protrusion found in most mechanosensory cells.

mollusks Animals whose soft body is surrounded by a more or less developed shell (mussels, snails, octopus).

nociceptor A receptor that, if stimulated, causes the sensation of pain.

prokaryotes Single-celled organisms that lack the formation of a distinct nucleus.

stereocillia Modified microvilli that contain large amounts of actin filaments.

TRP Transient receptor potential, a superfamily of ion channel proteins.

3.05.1 Introduction

Any cell can be stimulated by almost any stimulus, provided the intensity is high enough. Defining the appropriate stimulus therefore requires finding the stimulus that is able to drive a receptor cell with the least amount of energy. This is important even at the molecular level, where solely mechanosensitive channels (Msc) (Goodman, M. B. *et al.*, 2004; O'Hagan, R. *et al.*, 2005) and channels that can respond to other stimuli have been identified (Syntichaki, P. and Tavernarakis, N., 2004; Kung, C., 2005; Zhou, X. L. *et al.*, 2005). Mutations have identified a number of candidate genes in several metazoan taxa that may be part of a mechanosensory transduction complex, but only in the nematode *Caenorhabditis elegans* are we approaching a molecular understanding of this complex (O'Hagan, R. *et al.*, 2005). Indeed, and in contrast to bacteria (Sukharev, S. and Corey, D. P., 2004; Anishkin, A. and Kung, C., 2005), without this genetic approach to mechanosensory function we would likely not even have those metazoan candidate genes identified. Problems in identifying mechanosensory channels seem to relate to their generally low abundance compared to those for phototransduction (Ernstrom, G. G. and Chalfie, M., 2002), making isolation of their mRNAs and proteins nearly impossible with current techniques. In addition, these channels have no known specific ligand to facilitate other approaches for protein purification, as used for ligand-gated channel discoveries.

The best-understood channels in terms of molecular modeling (Chiang, C. S. *et al.*, 2004) are the tension-gated mechanosensitive channels (large and small Msc: MscL and MscS, respectively) in bacteria that respond to tension of 5–10 $\mathrm{dyn\,cm^{-1}}$ (or 5–10 $\mathrm{mN\,m^{-1}}$) along the membrane with an iris-like opening in 10 ns (Anishkin, A. and Kung, C., 2005; Kung, C., 2005). Such gating times could accommodate even frequencies of over 100 kHz, which is as rapid as transduction in mammalian cochlear hair cells (Hudspeth, A. J., 2005). Comparison of absolute sensitivity of membrane tension to channels that are tethered to accessory structures is difficult (Sukharev, S. and Corey, D. P., 2004) and could best be accomplished by calculating the work done in opening an MscL channel (approximately 2×10^{-19} J) and an auditory transduction channel (approximately 2×10^{-21} J). Such calculations suggest that the tethered vertebrate channel may be up to two orders of magnitude more sensitive than the untethered bacterial channel. Specifying the molecular details of such sensitivity differences is beyond our current knowledge. Nevertheless, it appears appropriate to first explore what is known about the mechanosensory channels of bacteria followed by the molecularly less well-known channels in multicellular organisms.

3.05.2 The Origin of Mechanosensation Lies in Untethered, Membrane-Tension-Gated Channels

Mechanotransduction is likely as old as living cells (archaea, bacteria (prokaryotes), and eukaryotes) and is mediated by a number of transmembrane channels that have only a limited degree of conservation across and within phyla (Blount, P., 2003; Syntichaki, P. and Tavernarakis, N., 2004; Tobin, D. M. and Bargmann, C. I., 2004; Kung, C., 2005). In its simplest form, mechanoreception monitors cell turgor with a channel that responds to membrane tension (Figure 1). Such mechanotransduction serves single-cell homeostasis. Based on the finding of tethering threads in vertebrate mechanosensors, it has been proposed that the ability of hair cell to perceive displacements of a few nanometers with forces of <10 pN (Hudspeth, A. J., 2005) depends on such tethers. Likewise, attachments have been found in other highly sensitive mechanosensors of flies and nematodes (Ernstrom, G. G. and Chalfie, M., 2002; Emtage, L. *et al.*, 2004; Gong, Z. *et al.*, 2004). It is possible that, in the course of evolution, untethered channels were modified to respond even more effectively to stimuli across the membrane by tethering them to other structures such as other parts protruding from the same cell, extracellular matrix, or the internal cell skeleton (Figure 1). Alternatively, tethered and untethered channels may have evolved independently. The limited molecular data on tethered channels, combined with the great variety of molecular candidates for mechanically gated channels, make it difficult to exclude any of these possibilities at this moment. Indeed, it has been suggested that candidates for tethered channels in metazoans are as multimodal as those in bacteria (Kung, C., 2005) and direct evidence exists that shows that reconstituted TRPC1 or TRPY channels can be gated purely by membrane tension (Maroto, R. *et al.*, 2005; Zhou, X. L. *et al.*, 2005). These hypothesized and known similarities of certain tethered and untethered channels indicate that there may not be major structural

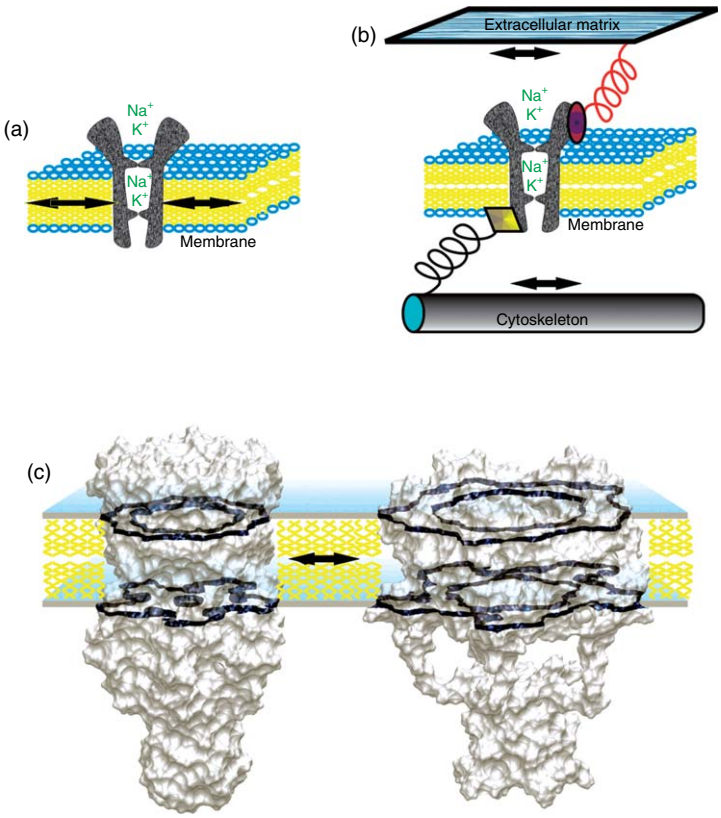

Figure 1 Various channels that respond to changes in turgor resulting in stretch of the membranes (double arrow in (a)) have been found in single-cell organisms. It is possible that such mechanosensitive channels (Msc) were modified in the unicellular ancestor of metazoans through extracellular or intracellular matrix attachments to provide increased sensitivity for shearing forces. Molecular evidence suggests that, across metazoans, only family members of degenerin/epithelial sodium channels (DEG/ENaC) and transient receptor potential (TRP) channel families are candidates for Msc. It thus remains possible that metazoan ancestors selected either or both families for specific properties that allow increased sensitivity to detect mechanical stimulations. What such properties could be remains unknown in the absence of any model of sensitive mechanosensory channel in any metazoan taxon. Detailed models of the pentameric large mechanosensitive channels (MscL) of bacteria suggest in iris-like opening upon tension acting in the plane of the membrane (c). Adopted from Chiang, C.S., Anishkin, A., and Sukharev, S. 2004. Gating of the large mechanosensitive channel *in situ*: estimation of the spatial scale of the transition from channel population responses. *Biophys. J. 86, 2846–2861,* with permission from S. Sukharev; and Syntichaki, P. and Tavernarakis, N. 2004. Genetic models of mechanotransduction: the nematode Caenorhabditis elegans. Physiol. Rev. 84, 1097–1153.

differences between those channels other than intra- and/or extracellular tethering.

Within recent years a number of candidates for untethered mechanotransduction channels have been molecularly defined in prokaryotes and eukaryotes (Blount, P., 2003; Syntichaki, P. and Tavernarakis, N., 2004). No sequence similarities exist between the Msc of prokaryotes and the likely Msc of eukaryotes, which belong to the degenerin/epithelial sodium channels (DEG/ENaC) and transient receptor potential (TRP) superfamily of genes (Goodman, M. B. *et al.*, 2004; Sukharev, S. and Corey, D. P., 2004; Tobin, D. M. and Bargmann, C. I., 2004; O'Hagan, R. *et al.*, 2005). In eukaryotes, TRP-like genes have also been found to form tension-sensitive TRP channels in yeast (Anishkin, A. and Kung, C., 2005; Kung, C., 2005; Zhou, X. L. *et al.*, 2005). Such tension-sensitive membrane channels therefore evolved before tethered mechanosensory channels, which appear to be restricted to fungi and multicellular animals. No DEG/ENaC channel has thus far been identified in fungi, suggesting that it evolved in metazoan ancestors (Figure 2). It is possible that different taxa of metazoa have recruited different channels or channel subunits to form specific Msc. Only the tethered mechanosensory channels are coupled with highly adaptable and not necessarily homologous connection(s) to accessory structures

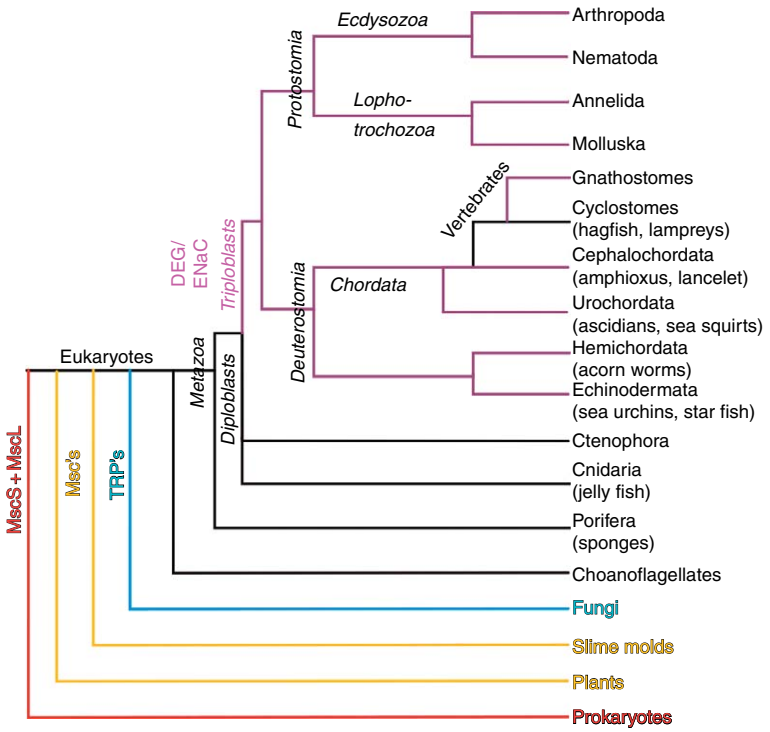

Figure 2 Distribution of the various known and putative mechanosensitive channels (Msc) is shown. All prokaryotes seem to share the large and small Msc (MscL and MscS, red). Plants and slime molds seem to have a variation of a modified form of this channel (Msc, yellow). There is no obvious sequence homology among these channels. Fungi and metazoans have transient receptor potential (TRP) channels, suggesting that the metazoan ancestors had at least this channel family (blue). Whether it functioned as a Msc remains unclear. At least triploblasts, but possibly all metazoa, have degenerin/epithelial sodium channels (DEG/ENaC) type of channels (lilac). As with TRP channels, it is unclear at which point they evolved into Msc. Adapted from Eichinger, L., Pachebat, J. A., Glockner, G., Rajandream, M. A., Sucgang, R., Berriman, M., Song, J., Olsen, R., Szafranski, K., Xu, Q., *et al*. 2005. The genome of the social amoeba *Dictyostelium discoideum*. Nature 435, 43–57; and Rokas A., Kruger, D., and Carroll, S. B. 2005. Animal evolution and the molecular signature of radiations compressed in time. Science 310, 1933–1938.

(Figure 1) that filter and amplify specific mechanical stimuli to enable a given mechanosensory cell to respond best to light touch, angular acceleration, gravity, or sound (Syntichaki, P. and Tavernarakis, N., 2004). This aspect is nowhere more obvious than in the various organs modified in vertebrates and invertebrates for sound energy detection (Sukharev, S. and Corey, D. P., 2004; Gillespie, P. G. *et al*., 2005; Hudspeth, A. J., 2005; Fritzsch, B. *et al*., 2006a).

Prokaryotic mechanosensitive multimeric channels share structural and functional similarities with the membrane-spanning domains (Figure 2). In contrast, eukaryotes have similarities only in the basic structural motifs (two membrane-spanning units) and membrane topology of these channels, in particular with the DEG/ENaC family of ion channels (Blount, P., 2003), as well as with the certain inward rectifying K^+ channels (Kung, C., 2005). Some of these similarities provide the basis for the multimodal sensitivity to heat, chemical stimuli, and osmolarity found in bacterial mechanosensors and TRP channels (Ernstrom, G. G. and Chalfie, M., 2002; Goodman, M. B. *et al*., 2004; Tobin, D. M. and Bargmann, C. I., 2004; O'Hagan, R. *et al*., 2005). In addition, it is noteworthy that the mammalian Shaker and other voltage-gated channels can also be modulated by membrane stretch, implying that, much like in the prokaryotic archaea and bacteria, both voltage changes and mechanical forces can activate the channel (Sukharev, S. and Corey, D. P., 2004; Kung, C., 2005).

The large conductance mechanosensitive channel (MscL) of bacteria has been shown to be a homopentamer with two iris-like openings at the extracellular and the intracellular sides. The size differences between the closed and the open states have been estimated to 23.3 nm^2 (Figure 1). Details of the movement are still debated, but it appears that most of the configuration change is a change in the position of

helices of domains near the lipid–water interface (Chiang, C. S. *et al.*, 2004; Tang, Y. *et al.*, 2006). It is possible that Msc can respond to either tension within the membrane or, if properly tethered, tension across the membrane. However, no reconstitution with a tether has been achieved in any channel to date, so the later assertion remains speculative.

In the following, we will explore the genetically identified candidates only for tethered channels and their variable, currently largely hypothetical, use in mechanotransduction. Specifically we will explore three main aspects of mechanosensory molecular and cellular evolution:

1. We will discuss the similarity and possible homology of presumed metazoan mechanosensory channels across the four main taxa where molecular data exist, the nematode *C. elegans* (Ce), the fly *Drosophila melanogaster* (Dm), the zebrafish *Danio rerio* (Dr), and the mouse *Mus musculus* (Mm).
2. We will put these molecular and structural data, including data on tethering molecules, into the context of our current understanding of mechanosensory cell and organ evolution and tethering to extracellular and intracellular structures.
3. We will discuss the molecular origin of hair cell transduction, with particular emphasis on mammals and what can be learned by comparison to other taxa.

3.05.2.1 Transient Receptor Potential and Degenerin/Epithelial Sodium Channels Genes of *Caenorhabditis elegans*, *Drosophila melanogaster*, *Ciona intestinalis*, *Danio rerio*, *Mus musculus*, and *Homo sapiens* Compared: Sequence Data Indicate Candidate Genes that Need to be Investigated

In the last 10 years, numerous putative mechanotransducer channels have been identified and their functions assessed. The emerging theme is that putative metazoan mechanosensory channels belong to the TRP or DEG/ENaC family of genes. With the completion of the genome of various vertebrates and invertebrates, it is now possible to establish sequence similarities and thereby assess whether a given gene is going through rapid sequence alteration even in closely related animals. Logically, given for example the ancient features of stereocilia in vertebrate hair cells that are responsible for mechanotransduction, one would like to find a putative channel that is at least conserved across vertebrates, if not shared with closely related deuterostome invertebrates such as *Ciona intestinalis* (Ci; Figure 2). Indeed, listing genes according to their conservation allows the identification of highly conserved as well as highly variable sequences (Table 1, Figure 3). Channel subunit homologies were determined based on current understanding of the known and predicted proteomes from these six species. It must be noted that the orthologs for both TRP and DEG/ENaC genes provided in Table 1 are not complete, since analyses of Dr and Ci genomes are still lagging behind in both the degree of completion of the genomic sequence and the subsequent annotation of the genes, transcripts, and predicted proteins (Okamura, Y. *et al.*, 2005).

The diversity among the members of the amiloride-sensitive cation sodium channels (ascNaC) superfamily is reflected primarily by the heterogeneity in the peptide sequences. However, the structural motif of these channels is highly conserved along with their generalized mechanoreception function. In comparison, the TRP superfamily is highly diversified, with a common channel motif being shared within each subfamily. This wide diversity is also highlighted by the extensive range of biophysiological and functional properties and use in rather diverse sensory stimulus acquisition. In order to emphasize this diversity, we will provide a summary of the members of each subfamily along with their associated channel properties and functional characteristics.

3.05.2.1.1 The transient receptor potential superfamily

The TRP superfamily of cation channels displays a wide range of gating versatility and associated functional properties. TRP channels play important roles in nonexcitable cells; however, an emerging theme is that many TRP-related proteins are expressed in the nervous system and function in sensory physiology. Most of the TRP channels are permeable for Ca^{2+} and in general provide Ca^{2+} influx pathways (Nilius, B. *et al.*, 2005). Members share a common structural motif that contains six putative transmembrane domains (TM1–TM6) with an intercalated pore (P) domain and the N- and C-terminal tails are located in the cytoplasm. Domains TM5, TM6, and P are thought to form the central cation-conducting pore, whereas TM1–TM4 and the cytoplasmic tails are proposed to contain the regulatory elements for channel formation and gating. The function of the

[a]The scoring matrix for BLASTP alignment of human TRP and DEG/ENaC proteins in comparisons with the orthologs from mouse, zebrafish, sea squirt, fly, and worm. The three numbers represent the percent homology of positive amino acid, the percent length of homologous peptide fragment per total length of the human peptide sequence, and the percent of sequence gaps within the region of homology.

[b]Comparisons were done between the Dm nan and the nompC proteins and their respective orthologs.

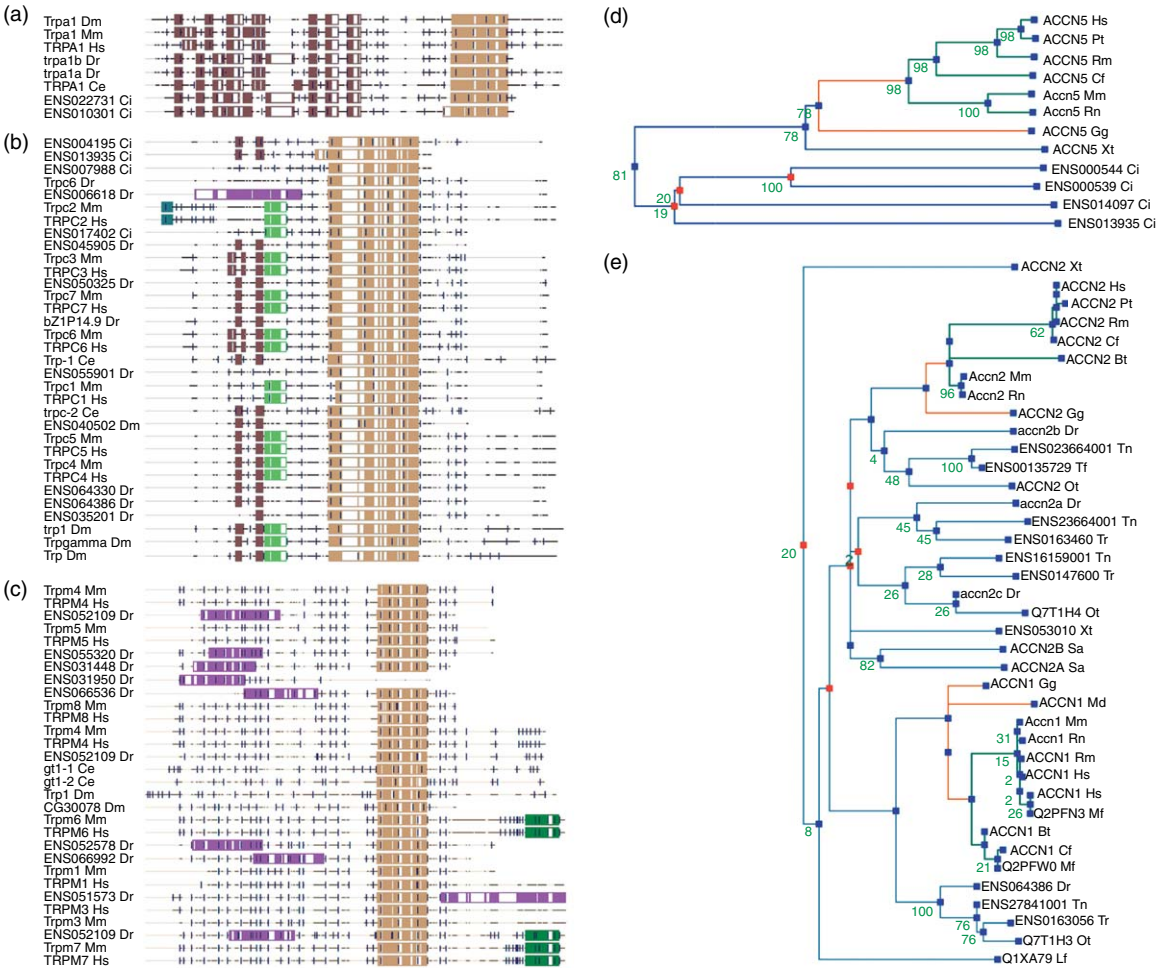

Figure 3 Similarities in channel proteins. The structural motifs of the orthologs and paralogs of the TRPA (a), TRPC (b), and TRPM (c) subfamilies are represented. Boxes correspond to protein family (Pfam) domains, while lines correspond to nondomain regions. Dark lines or boxes show matched parts, while light ones indicate homology gaps. Vertical dark-blue lines indicate splicing boundaries. The structural motifs represented are ion channel (■ – PF00520), transient receptor ion channel II (■ – PF08344), ankyrin repeat (■ – PF00023), IMP dehydrogenase/GMP reductase domain (■ – PF00478), α-kinase family domain (■ – PF02816), and XRCC1 N-terminal domain (■ – PF01834). A protein family tree is presented for the Accn5 (d) and Accn1/2 (e) orthologs where the full sequences were expanded from the seed through BLAST-HMMer pipeline and the full tree was reconstructed by constrained neighbor joining. The score in the TreeFam gene page is bootstrapping support rescaled around 100, where the higher the value the greater the homology. It measures how often the same ortholog (or within species paralog) pair can be inferred from a resampled tree.

N- and C-termini are still poorly understood. This general channel motif is similar to that associated with the family of voltage-gated potassium channels, except the S4 (TM4) membrane-spanning region does not contain positively charged amino acid R groups. Based on peptide sequence homologies and functional properties, these channels are grouped into seven subfamilies. The group 1 TRPs are the TRPC (canonical or classical), TRPV (vanilloid), TRPM (melastatin), TRPA (ankyrin), and TRPN (NOMP) channels and comprise closely related TRP subfamilies. Members of the group 2 TRP subfamilies, TRPML (mucolipin) and TRPP (polycystin), are distantly related to the group 1 TRPs. Each of these TRP subfamilies is represented by members in nematodes, flies and mice and provides the potential for using genetic approaches to characterize the normal functions and activation mechanisms of these channels.

In mammals the TRPC subfamily contains seven members that are all permeable for Ca^{2+} and are generally thought to mediate store-operated Ca^{2+}

entry (Montell, C., 2005). The selectivity P_{Ca}/P_{Na} ratio ranges from 1 for TRPC1 to 9 for the TRPC5 channels, and the conductance of the homomeric channels is 16 pS for TRPC1, 28–42 pS for TRPC2, TRPC4, and TRPC6, and ~65 pS for TRPC3 and TRPC5 (Nilius, B. *et al.*, 2005). It is suggested that these channels can also be activated by phospholipase C (PLC)-dependent pathways, but the precise mechanism of PLC stimulation still remains controversial. In addition, three channels, TRPC3, TRPC6, and TRPC7, appear to be activated by production of diacylglycerol in a manner that is independent of protein kinase C activity or regulated through an exocytotic mechanism (Trebak, M. *et al.*, 2003). These three subunits are homologous and do form heteromeric channels when expressed in human embryonic kidney (HEK) cells. Because of the functional redundancy of TRPC3/6/7, it may be necessary to generate double or triple nulls to examine their *in vivo* function. To date, only a *Trpc6*-null mouse line exists, and studies suggest that *Trpc3* expression increases as a compensatory mechanism (Dietrich, A. *et al.*, 2005). A nonredundant function for TRPC6 was identified in its role in controlling vascular smooth muscle tone. Missense mutations in the human *TRPC6* gene lead to a dominant form of focal segmental glomerulosclerosis (FSGS2) (Reiser, J. *et al.*, 2005; Winn, M. P. *et al.*, 2005) and cause a defective permeability barrier in the kidney, leading to renal failure. This pathology corresponds with TRPC6 being a component of the glomerular slit diaphragm associated with kidney podocytes.

Other functionally distinct heteromeric channels are formed by the closely related TRPC1, TRPC4, and TRPC5 subunits (Strubing, C. *et al.*, 2003). These genes are coexpressed in hippocampal neurons, but these paralogs are differentially expressed in most other tissues and cells (Freichel, M. *et al.*, 2004). *In vitro* expression studies have found that TRPC1 channels display an Msc-like membrane stretch activation, but whether or not the native TRPC1 channels exhibit this property still needs to be resolved. A TRPC1-null mutant mouse line that would permit testing this possibility has yet to be reported. Although TRPC1/4/5 subunits may compensate for each other, *Trpc4*-deficient mice exhibit loss of a store-operated Ca^{2+} current in vascular endothelial cells and an associated reduction in vasorelaxation capacity (Freichel, M. *et al.*, 2001; 2004). Unlike the other TRPC members, the TRPC2 has a highly restricted expression in neurons of the vomeronasal organ and in testis. Two independently derived knockout *Trpc2* mice found defective diacylglycerol-gated (DAG)-activated cation ion currents, a loss of sex discrimination among males and females, and male–male aggression (Leypold, B. G. *et al.*, 2002; Stowers, L. *et al.*, 2002).

The members of a second subfamily (TRPV) can be grouped into four highly related groups, which are TRPV1/2, TRPV3, TRPV4, and TRPV5/6. This TRP subfamily primarily functions in sensory physiology and responds to heat, changes in osmolarity, odorants, and mechanical stimuli. TRPV members 1–4 have a modest permeability for Ca^{2+} with a permeability P_{Ca}/P_{Na} ratio of ~1–10 whereas TRPV5 and TRPV6 are the only highly selective channels for Ca^{2+} ($P_{Ca}/P_{Na} > 100$) of all the TRP members (Clapham, D. E., 2003). The conductances of these homomeric channels are 35–90 pS for members 1, 4, –6, 190 pS for TRPV3, and TRPV2 has yet to be reported. Heat-activated TRP channels are primarily associated with TRPV1–4 and TRPM5 subunits and comprise one group of thermosensory channels (Nilius, B. *et al.*, 2005). The second group is the cold-activated TRP channels with TRPA1 and TRPM8. The range of temperatures (<10 to >50 °C) represented by these TRP channels corresponds with the physiological range of temperatures discriminated by humans. These channels are present not only in peripheral neurons and sensory fibers but also in the skin, with TRPV3 and TRPV4 primarily localizing to keratinocytes (Chung, M. K. *et al.*, 2003; Moqrich, A. *et al.*, 2005). Temperature sensitivity was verified in *Trpv1*-null mutants, where the mice are unable to respond to moderate heat (~43 °C), capsaicin, and lowering of pH (Caterina, M. J. *et al.*, 2000; Davis, J. B. *et al.*, 2000). TRPV1 also functions as a stretch receptor in bladder epithelial and urothelial cells with diminished responses to stretch and hyposmolal conditions in *Trpv1*-deficient mice (Birder, L. A. *et al.*, 2002). The TRPV2 and TRPV3 channels contrast with TRVP1 by their insensitivity to capsaicin and wider tissue distribution. TRPV3 is activated by temperatures ranging from 32 to 40 °C, which was confirmed in null mice (Moqrich, A. *et al.*, 2005). In comparison, TRPV2 channels respond to temperatures >52 °C and are associated predominantly with nociception. These data still need to be confirmed in *Trpv2* genetically altered mice. A rather surprising diversity of mechanosensory and nociceptive stimuli can activate TRPV4, which was confirmed in two independently produced null mutant lines (Liedtke, W. and Friedman, J. M., 2003; Suzuki, M. *et al.*, 2003). Interestingly, these mice also lose their hypotonicity responses and avoidance of

noxious odorants, which is similar to the worm mutants of osm-9 (Liedtke, W. *et al.*, 2003). Although there is functional homology between these two channels, a similar homology between their proteins is not apparent. Because of the high Ca^{2+} permeability of the TRPV5 and TRPV6 channels, these two paralogs are essential for Ca^{2+} homeostasis, with TRPV5 being essential for reabsorption in bone and TRVP6 found in the intestine. These two subunits can form heteromultimers. This has resulted in compensation by TRPV6 in *Trpv5*-deficient mice and has produced a milder bone phenotype with only a reduced bone thickness (Hoenderop, J. G. *et al.*, 2003). However, investigation of compensatory mechanisms between TRPV5 and TRPV6 still awaits the production of a *Trpv6*-null mouse line.

The TRPM subfamily members represent a functionally diverse set of channels. All the homomeric channels have a P_{Ca}/P_{Na} selectivity of 0.5–3 and conductances within the 40–130 pS range, except for TRPM4 and TRPM5, which have no cation selectivity and a conductance of 16–25 pS (Nilius, B. *et al.*, 2005). TRPM1 was the first channel identified and was initially named melastatin for its expression in highly metastatic melanoma cell lines. Further characterization of this channel is currently hindered by the difficulty of recording TRPM1 currents and the lack of identification of mutated forms of this gene in both humans and mice. The functional assessment of TRPM3 suggests that the channel current is nonselective, constitutively active and responsive to hypotonic stimuli with possible store-operated Ca^{2+} entry properties (Kraft, R. and Harteneck, C., 2005). TRPM3 is expressed in the kidney and nervous system. Like TRPM1, no mutant TRPM3 genes are presently known. The TRMP4 and TRMP5 channels are similar in being impermeable to Ca^{2+}, form ion channels permeable to monovalent cations, and are candidates for endogenous calcium-activated cation channels (Nilius, B. *et al.*, 2005). However, they are functionally very different. TRMP4 appears to be involved in negative-feedback regulation and release of interleukin 2 from T lymphocytes (Launay, P. *et al.*, 2004). In contrast, TRPM5 is highly expressed in taste receptors cells and, as demonstrated in *Trpm5*$^{-/-}$ mice, is essential for detection of sweet, bitter, and umami taste stimuli (Zhang, Y. *et al.*, 2003).

Besides TRPM5, the only TRPM member conveying sensory sensation is the TRPM8 channel, a thermosensory channel that is activated by temperatures <25 °C or cooling compounds such as menthol and icilin (Peier, A. M. *et al.*, 2002; Reid, G., 2005). Three TRPM proteins, TRPM2, TRPM6, and TRPM7, are classified as chanzymes, since these subunits contain a C-terminal α-kinase enzyme domain. TRPM2 is unique in possessing ADP-ribose hydrolase activity and appears to function as a sensor for cellular redox status by playing a role in responses to oxidative and nitrosative stresses (Perraud, A. L. *et al.*, 2005). Both TRPM6 and TRPM7 are similar, being involved in Mg^{2+} homeostasis, with TRPM7 playing an additional role in neuronal cell death (Levitan, I. B. and Cibulsky, S. M., 2001; Aarts, M. *et al.*, 2003). TRPM6 is predominantly expressed in the kidney and the gastrointestinal system, whereas TRPM7 is ubiquitously expressed. Null mutant mice are still needed to validate and extend functions of these three chanzymes.

The fourth and fifth subfamilies, TRPA and TRPN, include proteins with many ankyrin repeats. TRPN proteins function in mechanotransduction, whereas TRPA1 is also activated by noxious cold (Walker, R. G. *et al.*, 2000; Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006; Li, W. *et al.*, 2006). The TRPA subfamily has only one member, *TRPA1*, and this gene is highly conserved and present in all species examined. The cytoplasmic N-termini of the TRPA1 orthologs contained 14–15 ankyrin domains. TRPA1 channels have a P_{Ca}/P_{Na} selectivity of 0.8–1.4 and a conductance of 40–105 pS and are expressed in sensory neurons and inner ear hair cells (Story, G. M. *et al.*, 2003; Corey, D. P. *et al.*, 2004; Nagata, K. *et al.*, 2005). Two independently derived null mutant mouse lines established that TRPA1 channels are activated by noxious cold and pungent substances, but the proposed role as the hair cell mechanically gated transduction channel was not validated (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006). The TRPN subfamily contains a single member that is unique from the other TRPs with the presence of 29 ankyrin motifs in the cytoplasmic amino tail (Walker, R. G. *et al.*, 2000). In mammals, the TRPN1 ortholog gene appears to be deleted from the genome. TRPN1 orthologs are present in the ciliated neurons of Ce and Dm, Dr, and in Xenopus hair cells (Walker, R. G. *et al.*, 2000; Sidi, S. *et al.*, 2003; Shin, J. B. *et al.*, 2005). In addition, frog TRPN1 channels were also localized to microtubule-based cilia in epithelial cells. Loss-of-function mutants resulted in the absence of mechanotransduction in the ciliated sensory neurons of worms and sensory bristles of flies (Walker, R. G. *et al.*, 2000). Morpholino-mediated removal of TRPN1 in

zebrafish eliminated transduction-dependent electrical responses in HCs (Sidi, S. *et al.*, 2003). Comparative genomics identify a single TRPN1-like gene in Ci.

The group 2 TRP subfamilies are responsible for human mucolipidosis type IV (MCOLN1) and polycystic kidney (PKD1 and PDK2) diseases. The three mammalian members, MCOLN1–3, of the TRPML subfamily have similar structural motifs, with a lipase domain between TM1 and TM2, a nuclear localization signal, and a putative late endosomal–lysosomal targeting signal. Functional assessment of these channels has been reported only for MCOLN1 channels, where the P_{Ca}/P_{Na} selectivity is ~1 and conductance is 46–83 pS. Mutations in the *MCOLN1* gene causing mucolipidosis type IV are primarily nonsense and deletions and result in premature termination of the protein. Missense mutations are also described and occur in the cation ion domain or prevent MCOLN1 channels to localize to late endosomes. Mouse mutants of *Mcoln1* and *Mcoln2* genes have yet to be reported. Interestingly, two spontaneous mutations in the varitint-waddler mouse *Mcoln3* gene cause deafness with pigmentation defects (Di Palma, F. *et al.*, 2002). MCOLN3 channels were found in the cytoplasmic compartments of hair cells and plasma membrane of stereocilia. Although correlation of pigmentation defects and deafness is observed in humans, the direct relationship between hearing and regulation of pigmentation is fully resolved in each case. Replication of the TRPML gene apparently occurred in vertebrates with only one ortholog found in the nonvertebrate species.

Four mammalian paralogs were identified in the TRPP subfamily with the homology among orthologs and paralogs appearing to reside primarily in polycistin domains (Delmas, P., 2005). Channel P_{Ca}/P_{Na} selectivity for the TRPP channels ranges from 1 to 5 and conductances of 44–300 pS. Although the polycystin domain is present in a number of genes, only the PKD1, PKD2, PKD2L1, and PKD2L2 orthologs have a cation ion channel domain. Null mutations in the mouse *Pkd1* and *Pdk2* genes have polycystic kidney disease and die *in utero* (Morsli, H. *et al.*, 1998; Boulter, C. *et al.*, 2001). Autosomal dominant polycystic kidney disease in man is caused by *PKD1* and *PKD2* mutations in genes, with majority of these mutations involving frame shift or nonsense mutations that lead to a premature termination of the proteins (Al-Bhalal, L. and Akhtar, M., 2005). Both these paralogs are ubiquitously expressed whereas the tissue distribution of PKD2L1 and PKD2L2 is more restricted, with PKD2L2 being highly expressed in the testis. PKD2L1 was found to form functional channels when expressed with PKD1 in a heterologous expression system. Interestingly, heteromeric channels composed of subunits of PKD2L1 and PKD1L3, which lacks the cationic ion channel domain, are candidates for sour taste receptors (Ishimaru, Y. *et al.*, 2006; LopezJimenez, N. D. *et al.*, 2006). Mutations in the *PDK2L1* and *PKD2L2* genes have yet to be identified to facilitate their characterization.

Representative members of each family are present in Mm and *H. sapiens* (Hs), with both sharing common orthologs with a high homology for all the members of the TRP superfamily. In comparison, Dr TRP subfamilies are similar to those of the mammal with the exception of a single member in the Dr TRPV subfamily and the presence of a TRPN gene, for which a suitable ortholog for mammals has yet to be identified. The superfamily representations in Ce, Dm, and Ci are very similar, although there are variations in both number of members and orthologs. It appears that expansion of the TRP superfamily occurred in vertebrates, accompanied by utilization in a wide variety of biological functions. Only two TRP members, TRPA1 and the TRPM MCOLN1, appear to be highly conserved across species.

Figures 3(a)–3(c) depicts the variation in structural motifs represented by members of the TRPA, TRPC, and TRPM subfamilies. Even within the conserved ion channel motif, there is significant variation among the members within a subfamily and between orthologs. This diversity is also reflected in the composition of additional structural motifs, such as the ankyrin repeat, transient receptor ion channel II, IMP dehydrogenase/GMP reductase, α-kinase, and XRCC1 N-terminal domains, within the TRPC, TRPA, and TRPN subfamily members. The number of ankryin repeat domains is increased in number from 3 to 4 in the TRPC genes, 14 to 15 in TRPA1, to ~29 for the TRPN orthologs. Use of the IMP dehyrogenase/GMP reductase domain appears to be a unique adaptation in the *Drosophila*, whereas the XRCC1 N-terminal domain is only present in the mammalian TRPC2 orthologs.

Further functional diversity can also be generated by formation of homo- and heterotetrameric channels, with homomeric channels usually being favored (reviewed in Schaefer, M., 2005). The configurational mechanisms, affinity among the subfamily members, and possible

heteromeric assembly between the subfamily members are currently being systematically studied.

3.05.2.1.2 The degenerin/epithelial sodium channels superfamily

In comparison to diversity observed in the TRP superfamily members, the members of DEG/ENaC family are more conserved in that they contain only an amiloride-sensitive cation (asc) channel motif (reviewed by Kellenberger, S. and Schild, L., 2002). This motif contains two TM regions with an intercalated pore domain. This domain is similar to that of the inward rectifier and twin-pore potassium ion channel subunits. However, this is where the conservation ends, since phylogenetic and sequence comparison demonstrate that the DEG/ENaC family has little to no sequence conservation among the nonmammalian species (see Tree families database). In Ce, there appear to be two conserved but distinct groups of ascNaC. Group 1 includes the original mechanosensitive sodium channel genes, *mec-4* and *mec-10* (Goodman, M. B. and Schwarz, E. M., 2003). In *Drosophila*, the ascNaC family is represented by an expansion of the pickpocket genes (Sukharev, S. and Corey, D. P., 2004). Orthologs of these genes are not found in the other species examined.

The ACCN subfamily of ascNaC genes is represented in Ce, Dr, Mm, and Hs. This family of channel subunits appears in the deuterostome invertebrates and five members exist in mammals. As depicted in Figure 3, the members of the ACCN5 subfamily are highly conserved across species, including the sea squirt, but surprisingly are absent in the zebrafish. Similar to the ascNaC in worms and flies, each of the ACCN subfamilies is distinct with little homology among the subfamilies. The ENaC or SCCN subfamily consists of three to four members. There is a high degree of similarity among both the orthologs and the paralogs of this subfamily. The prevailing model suggests that ascNaC are composed of four subunits, with both homo- and heterotetrameric configurations being formed. Mutational and biochemical data suggest that the ENaC SCNN1A, B, and G subunits form a functional channel as indicated by patients with pseudohypoaldosteronism type I and Liddle syndrome with mutations in any of these genes. Systematic efforts to examine heteromeric assembly between subfamily members of the TRP channels are under way (Sukharev, S. and Corey, D. P., 2004); similar studies of the DEG/ENaC superfamily interaction need to be pursued. The most extensive studies of DEG/ENaC channel interactions with other proteins are available for the *mec-4/10* ascNaC channel associated with touch sensation in the worm (Goodman, M. B. and Schwarz, E. M., 2003).

In summary, the current data on TRP and DEG/ENaC channels suggest that each superfamily shares some transmembrane motifs across taxa, evolved in fungi and possibly early metazoan ancestors, respectively, and plays roles in sensing of several stimuli through altering, in an as yet poorly known way, their pore properties. Sequence similarities suggest evolution of distinct units in several lines, with only closely associated taxa such as vertebrates showing high level of similarities. Only few units are conserved across metazoans, suggesting that involvement in mechanosensation does not massively constrain their sequences.

3.05.2.2 Ancestry of Specialized Mechanosensory Cells

Mechanosensation has been claimed to be the basis of gravity sensing in single-cell organisms to avoid sinking to the bottom (gravikinesis) (Syntichaki, P. and Tavernarakis, N., 2004) and likely precedes the evolution of multicellular organisms. Given the likely molecular ancestry of eukaryotic mechanosensory channels, it is not surprising that mechanosensation has been claimed for virtually all multicellular (metazoa) organisms. Despite this generally agreed-upon molecular ancestry, there are problems in establishing cellular identity because of anatomical differences between functionally comparable mechanosensory organs – such as acoustic organs – across phyla. Certainly, not all the various members of the two main families of mechanosensory channel candidate genes have been mutated to assess their function, and some mutations turned out to be early lethal, precluding thereby their functional evaluation. In addition, even when candidate molecules were identified through lack of function in mutants, direct test of function proved extremely difficult, as both the channel and the tether to extra- and intracellular structures (to provide the necessary gating tension and improved sensitivity) have to be molecularly defined and reconstituted in a heterologous system. Moreover, it is possible that a channel is composed of multiple units that may allow functional substitution of a single lost unit by others, thus rendering the past approach problematic at best and unsuccessful at worst. To date, not a single tethered mechanosensory channel candidate has passed this most stringent of all tests. All current

data on the putative function of tethered mechanosensory channel candidates rely on loss of function or correlative evidence, and must therefore be viewed as tentative. In this respect, the nematode mechanosensory channel is perhaps the best defined (O'Hagan, R. *et al.*, 2005). Recent success in identifying the TRPC1 stretch-activated channel through protein purification and characterization in a heterologous expression system indicates that possibly other Msc can be identified through such approaches (Maroto, R. *et al.*, 2005). Likewise, comparative mutagenic analysis of gating properties of DEG/ENaC channels demonstrated the power of a combined approach to specify functionally relevant parts for proton sensitivity of this channel (Coric, T. *et al.*, 2005).

Nevertheless, loss of function through mutational analysis was essential to identify several candidate genes in various animals, which are difficult to reconcile with each other in terms of conservation of structure and function (see TRP and DEG/ENaC genes of *C. elegans*, *D. melanogaster*, *C. intestinalis*, *Danio rerio*, *Mus musculus*, and *Homo sapiens* Compared: Sequence Data Indicate Candidate Genes that Need to be Investigated). With this caveat in mind, it appears as of this writing that, at a molecular level, different channels belonging to either the DEG/ENaC/BNaC or the TRP families have been incorporated into highly sensitive mechanoreceptors, indicating that the morphology of mechanosensory cells and organs may be intricately interwoven with molecularly and functionally distinct channels and tethers.

3.05.2.2.1 Known or suspected mechanosensory cells of multicellular animals

As with the mechanosensory channels, two ideas prevail for mechanosensory cell and organ evolution. The structural dissimilarities between them has been interpreted as either (1) an indication of independent evolution (Coffin, A. *et al.*, 2004; Holland, L. Z., 2005) at the cell and organ level or (2) a variation on a common theme at a cellular level accompanied by independent arrangement at the organ level (Jorgensen, J. M., 1989; Fritzsch, B. *et al.*, 2006a). For this review we will focus on known or suspected mechanosensory cells that show potential extracellular tethering with possibly molecularly dissimilar compounds. While such tethered channels may already play a role in single-cell organisms, we will not explore this possibility here.

Recent molecular evidence has clarified that choanoflagellates are the unicellular ancestor of all multicellular animals (King, N. and Carroll, S. B., 2001; Lavrov, D. V. *et al.*, 2005; Rokas, A. *et al.*, 2005; Steenkamp, E. T. *et al.*, 2006). These unicellular organisms have a single beating kinocilium with $9+2$ microtubules, surrounded by microvilli that are interconnected by filaments in several species. Choanoflagellates use the beating kinocilium to drive water through the mesh formed by the interconnected microvilli to catch microbes for consumption (King, N., 2005). In addition, choanoflagellates can secrete a mineralizing extracellular matrix in which the cell is embedded, much like a snail in its shell. It is conceivable that tethered channels exist either at the base of tethers between the extracellular matrix and the cell or at the base of the tethers that interconnect the microvilli. Also, intracellular tethers could exist in members of the myosin family, such as MyoVII. Indeed, these myosins have already been suggested to anchor mechanosensory channels to the cytoskeleton in slime molds (Eichinger, L. *et al.*, 2005) and clearly predate the evolution of multicellular organisms and specialized mechanosensory cells. Barring more detailed genomic analysis, mechanosensory channel proteins related to TRPs, as well as unrelated mechanosensory channels, exist in single-celled eukaryotic organisms such as yeast and slime molds (Eichinger, L. *et al.*, 2005; Kung, C., 2005). Thus TRP channels had to be present in the unicellular ancestors of metazoans (Figure 2). Some of the molecules also thought to play a role in tethering in mammals, such as cadherins (Gillespie, P. G. *et al.*, 2005; Senften, M. *et al.*, 2006), exist in those unicellular eukaryotes. It is possible that the entire channel/tether assembly is conserved across unicellular ancestors of metazoans. More molecular analysis of unicellular organisms is needed to fully understand the molecular basis of mechanosensation.

Various epidermal sensory cells exist in diploblastic and triploblastic metazoan organisms, and in some taxa they are grouped into organs suspected or known to be mechanosensory (Figure 4). For example, coelenterates (jellyfish and corals) have gravistatic sensors composed of more or less polarized microvilli bundles surrounding a single, immobile kinocilium (Arkett, S. A. *et al.*, 1988). Spiders have complex, lyriform slit organs with which they can detect minute vibrations elicited by prey captured in their webs (French, A. S. *et al.*, 2002; Hossl, B. *et al.*, 2006). The mechanotransducing elements are amiloride-sensitive (French, A. S. *et al.*,

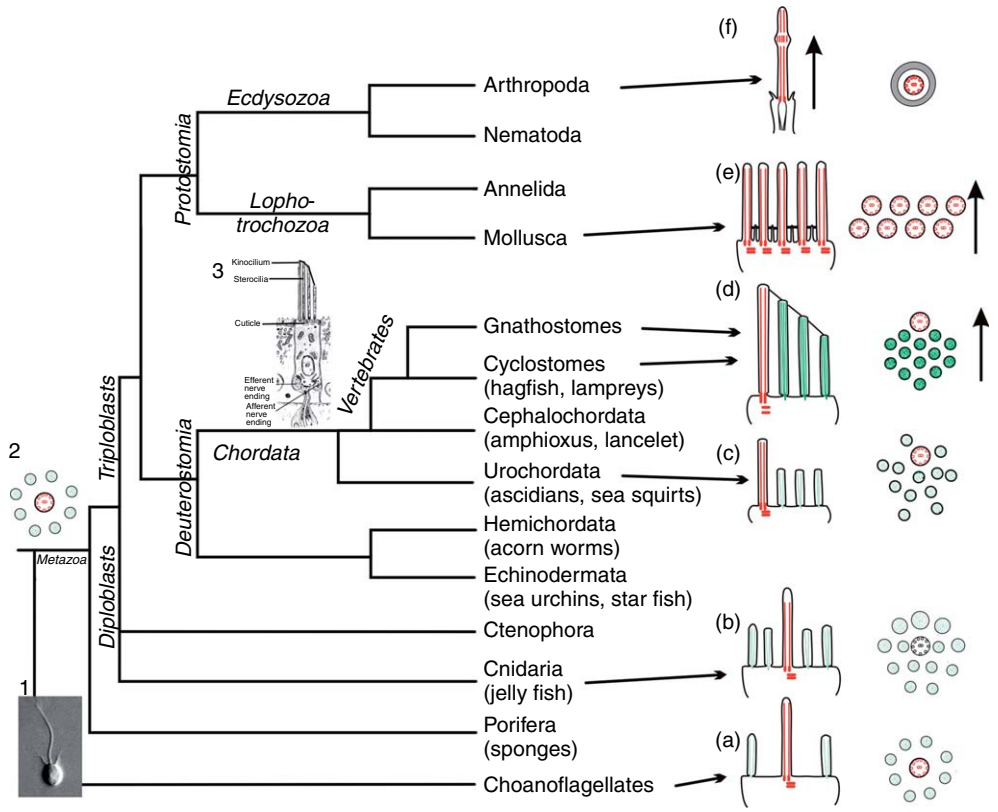

Figure 4 Kinocilia (red) and microvilli (light blue) of known or suspected mechanosensory cells in various eukaryotic unicellular and multicellular organisms are shown. Note that the single-celled ancestor of all multicellular animals, the choanoflagellates, has a single, actively beating kinocilium surrounded by microvilli that carry an actin core (a). In some diploblasts, the central kinocilium is surrounded by an asymmetric assembly of microvilli of various diameters, potentially providing directional sensitivity (b). Among deuterostomes, urochordates have various presumed mechanosensory cells that have a kinocilium with asymmetrically arranged microvilli (c). Vertebrates are unique in that a highly polarized, organ-pipe assembly of actin-rich stereocilia is attached via tip links with each other and the asymmetrically placed kinocilium (d). Among protostomes, mollusks may have numerous, interconnected kinocilia on mechanosensory cells (e). Ecdysozoans have either mechanosensory cells with cilia or a kinocilium that is stretched by the stimulus (f). Arrows indicate the direction of stimulation. Adapted from Fritzsch, B., Pauley, S., Feng, F., Matei, V., and Nichols, D. H. 2006b. The evolution of the vertebrate auditory system: transformations of vestibular mechanosensory cells for sound processing is combined with newly generated central processing neurons. Int. J. Comp. Psychol. 19, 1–24.

2002) and resemble in that respect mechanotransduction in many other taxa (Syntichaki, P. and Tavernarakis, N., 2004). Mollusks have statocysts, which have evolved into complex angular and linear perception detection organs that in cuttlefish rival the ears of vertebrates in their sensitivity (Budelmann, B. U., 1987). Cuttlefish also have hydrodynamic receptors that resemble the vertebrate lateral line (Budelmann, B. U. and Bleckmann, H., 1988; Budelmann, B. U. and Williamson, R., 1994). However, in contrast to vertebrates, the single sensory or neurosensory cells have apical specializations consisting of multiple kinocilia that are interconnected with each other near the base, possibly to activate tethered mechanosensory channels of unknown molecular composition. In multicellular organisms, there are many more examples of organizations that seem likely to provide an asymmetric mechanical input to tethered mechanosensory channels (Burighel, P. *et al.*, 2003; Mackie, G. O. and Singla, C. L., 2004; Fritzsch, B. *et al.*, 2006a).

Based on obvious cellular adaptations, it was proposed to distinguish between ciliated and nonciliated mechanosensory cells and some correlation between TRP and ciliated cells was noticed (Eberl, D. F. *et al.*, 2000; Goodman, M. B. *et al.*, 2004). Recent data suggest that mechanosensitive TRP channels exist in nematodes on ciliated and nonciliated cells (Li, W. *et al.*, 2006). Other variations of apical specializations can also be used to generate a different grouping. Most putative and known invertebrate mechanosensory

cells seem to be a variation of one basic organization, a kinocilium surrounded by microvilli (Jorgensen, J. M., 1989; Fritzsch, B. *et al.*, 2006b). Notable exceptions are the mollusks and the ecdysozoa (insects, nematodes, spiders, and crustaceans; Figure 4). In contrast to other multicellular organisms, ecdysozoans have an exoskeleton that leaves only limited openings for gas, water, and food exchange. It is possible that the evolution of this exoskeleton forced a radical reorganization of the mechanotransducer system: instead of variations on the theme of kinocilium and microvilli, these organisms have sensors with connections to the extracellular matrix that generate a force along a process rather than between different processes (Figure 4). Nevertheless, common features exist, such as the use of a kinocilium or special intracellular and extracellular tethering molecules, indicating that even these highly divergent forms may present derivations from the common theme of ancestral mechanosensory transduction (Figure 4). Tetrapod vertebrates, and in particular mammals, have also evolved mechanosensory transducers of various cellular compositions, such as Pacini and Meissner corpuscles, Merkel cells, and muscle spindles. In all these cases, the molecular basis for mechanosensation begins to emerge (Sukharev, S. and Corey, D. P., 2004), but a meaningful comparison with the evolutionarily ancestral mechanosensory cell, the vertebrate hair cell, is not possible in the absence of detailed information on the Msc in the latter cells. In summary, it appears that a distinction between ecdysozoans and nonecdysozoans can be made with respect to modifications of an ancestral kinocilum/microvilli specialization or with respect to a radical departure thereof.

Unfortunately, the genomes of only a few animals have been sequenced thus far, or the existing genome has not yet been fully annotated, and therefore the molecular composition of neither the mechanosensory channel nor the tethers can be assessed. Most of these organisms are unlikely to be used for genetic analyses comparable to those performed in the nematode (Ernstrom, G. G. and Chalfie, M., 2002; Goodman, M. B. and Schwarz, E. M., 2003), the fly (Kernan, M. *et al.*, 1994), the zebrafish (Sidi, S. *et al.*, 2003; Nicolson, T., 2005), or the mouse (Bryant, J. E. *et al.*, 2005; Gillespie, P. G. *et al.*, 2005). We will therefore limit our analysis to these four organisms (*C. elegans, D. melanogaster, D. reiro, M. musculus*) in which the putative mechanosensory elements have been molecularly identified and loss-of-function evidence exists for mechanosensory function.

3.05.2.2.2 Mechanosensory cells in Caenorhabditis elegans: connecting degenerin/epithelial sodium channels channels to the cuticle?

In *C. elegans*, numerous experiments have identified the cells, their structure, their development, and the mechanosensory channels that mediate fine touch such as elicited by a hair (Ernstrom, G. G. and Chalfie, M., 2002; Goodman, M. B. and Schwarz, E. M., 2003; Syntichaki, P. and Tavernarakis, N., 2004; Tobin, D. M. and Bargmann, C. I., 2004). Specifically, there are two pairs of anterior and posterior neurons and two ventral neurons that provide a total of six neurons that respond to light touch. In addition, these animals have two ciliated neurons that respond to light touch to the anterior pole, but these cells are polymodal nociceptors (Tobin, D. M. and Bargmann, C. I., 2004). If the six fine-touch mechanosensory neurons are ablated by lasers, the animals lose their ability to respond to mechanical stimuli along the body but are not otherwise negatively affected. The dendritic processes of all six cells run below and are interconnected to the extracellular matrix and the cuticle. Among neurons, these processes are uniquely characterized by unusual microtubules consisting of 15-protofilament microtubules (instead of the usual 13) that may provide a rigid internal core for mechanosensation. Eliminating only those 15-protofilament microtubules in *mec*-7 mutants, while maintaining other microtubules, leads to normal differentiation of sensory neurons but generates a 17-fold smaller mechanoreceptor current (O'Hagan, R. *et al.*, 2005). This indicates that the heavily crosslinked 15-protofilament microtubules play some role in increasing mechanosensation as previously suggested (Ernstrom, G. G. and Chalfie, M., 2002; Goodman, M. B. *et al.*, 2002). However, recent data (Emtage, L. *et al.*, 2004) suggest that extracellular tethering alone may suffice for mechanotransduction, with the 15-protofilament tubules adding increased sensitivity, possibly by providing added stiffness. Direct measurements of stiffness of the dendrite with or without these specialized microtubules are needed to resolve this question.

Mutational analysis has identified a total of 15 *mec* genes (mechanosensory abnormal) that can, if mutated, eliminate or significantly reduce fine-touch mechanosensation. Specifically, *mec-4* and *mec-10*, each coding for two closely related DEG/ENaC proteins, are expressed in the light-touch neurons, and the MEC-4 protein colocalizes with MEC-4 and MEC-6 proteins (Emtage, L. *et al.*, 2004). Most importantly, in the *mec-4* or *mec-10* mutants the mechanosensory neurons can still

respond to harsh touch, supporting the hypothesis that these genes code for essential units of the mechanosensory channel that specifically mediate light touch. Expression analysis in oocytes has shown that the channel is likely composed of two different DEG/ENaC units (MEC-2 and MEC-10) and two accessory proteins encoded by MEC-4 and MEC-6 (Goodman, M. B. *et al.*, 2002). Additional mutations that cause loss of fine-touch sensitivity are mutations in extracellular matrix components, in microtubules, and in genes necessary for the differentiation of mechanosensory cells (a bHLH gene, *lin-32*; a POU domain gene, *unc-86*; a LIM domain gene, *mec-3*). Such defects are caused by disrupted development and only indirectly relate to mechanosensory function, a general problem of mutational analysis. More targeted genes and conditional mutational approaches are needed to overcome this problem.

Single-cell recording (O'Hagan, R. *et al.*, 2005) has shown that the MEC-4/10 ion channel responds to force faster than the fastest known second messenger cascade and thus are likely recordings from a directly gated mechanosensory channel, a crucial verification of the basic assumption underlying the field (Ernstrom, G. G. and Chalfie, M., 2002; Goodman, M. B. and Schwarz, E. M., 2003). The mechanoreceptor currents are carried by Na^+ and can be blocked by amiloride, consistent with a mechanically gated DEG/ENaC channel type. It has been estimated that a single channel may exist at each focal point where the extracellular matrix and the neurite interact. The number of channels may be identical to the number of contact points of the dendrite with the cuticle. Despite all this progress, crucial molecular details of the channel (how many MEC-4 and MEC-10 units are assembled) and interaction with matrix (details of attachment to which unit of the channel) or attachment to the intracellular matrix (if attached at all) are unknown.

There are some similarities between the *C. elegans* mechanosensors and nonciliated mechanosensors in other taxa (such as the lyriform slit organs of spiders (French, A. S. *et al.*, 2002), the frog muscle spindles, and the Pacinian corpuscles of mammals) that may indicate that all these receptor cells use DEG/ENaC channels for mechanotransduction (Goodman, M. B. and Schwarz, E. M., 2003; O'Hagan, R. *et al.*, 2005). Several DEG/ENaC vertebrate genes have been mutated without any apparent effect, suggesting that either other mechanosensory systems such as the hair cells of the ear or the lateral line organs do not use DEG/ENaC channels for mechanosensation. Alternatively, and since not all these channels have been systematically mutated in any given vertebrate (and some mutations are neonatal lethal), it is possible that partially functional or normally functioning channels will form even if one unit is missing. Some DEG/ENaC channels are found in free nerve endings but also in endings at Meissner corpuscles, Merkel cells, hair follicles, and baroreceptors (Drummond, H. A. *et al.*, 1998; Price, M. P. *et al.*, 2000; Garcia-Anoveros, J. *et al.*, 2001; Sukharev, S. and Corey, D. P., 2004). Clearly, more work is needed before this circumstantial evidence is solid enough to warrant speculations about a uniform involvement of DEG/ENaC channels in mechanosensation across phyla.

3.05.2.2.3 *Genetics of mechanotransduction in Drosophila melanogaster*: tethering a kinocilium to the cuticle

Many fly mutants have defects in mechanosensory potentials and are grouped into the *nomp* (no mechanoreceptor potential) or *remp* (reduced mechanoreceptor potential) categories (Kernan, M. *et al.*, 1994). Cloning has identified several candidate genes involved in mechanosensory transduction, three of which belong to the TRP gene family. One of these is the TRPN channel, *nompC*, which has orthologs in nematodes, sea squirts, and zebrafish but not in mammals. *nompC*-null flies lose about half of their chordotonal organ sensitivity, and NOMPC may play an exclusive role in bristle mechanotransduction (Walker, R. G. *et al.*, 2000), but not in chordotonal organs such as the fly hearing organ (Eberl, D. F. *et al.*, 2000). Evidence suggests that NOMPC might form heteromultimers, but such channels have not yet been directly demonstrated. NOMPC has been proposed to connect via 29 ankyrin repeats to the cytoskeleton, thereby aiding in mechanotransduction of bristles and chordotonal organs (Walker, R. G. *et al.*, 2000). Another gene, *nompA*, eliminates, if mutated, all mechanosensation in bristles and chordotonal organs (Eberl, D. F. *et al.*, 2000). It was shown that this comes about by disrupting contacts between sensory neurons and cuticular structures, thus likely interfering with tethering of the dendrite (Chung, Y. D. *et al.*, 2001). Based on the differences between neuron and cuticular attachment, it was recently proposed that the different phenotypes of the *nompC* null in chordotonal organs and bristles relates to the attachment and thus indirectly to *nompA* (Gong, Z. *et al.*, 2004). *nompA* has sequence similarities to zona pelucida proteins and the N-terminal (N) domains of plasminogen/hepatocyte growth factor

proteins. Such domains fulfill diverse biological functions by mediating protein–protein or protein–carbohydrate interactions.

Two TRPV channels were recently shown to be essential for hearing in flies, *nanchung* (*nan*) and *inactive* (*iav*, the protein of the gene CG4536). Based on the loss of hearing in either *nan* or *iav* mutants, it has been suggested that both *nan* and *iav* contribute to the same complex. Green fluorescent protein (GFP)-labeled IAV is found in the proximal part of the cilium, whereas NOMPA is in the dendritic cap (secreted by the scolopale cell), requiring that the force transmission to NAN and IAV either pass through the cilium, possibly through the ciliary membrane, or be transmitted through the scolopidial space (Gong, Z. *et al.*, 2004). More work is needed to verify which of these modes of force transmission applies and whether NAN and IAV are indeed the channel(s) or yet another essential link in the force transmission chain (Gopfert, M. C. *et al.*, 2006).

More recently, it was found that mutation of the unconventional myosin VIIa fly ortholog, *crinkled* (*ck*), results in disorganization of the cilium and disruption of the scolopidia, and renders flies deaf (Todi, S. V. *et al.*, 2005). This work demonstrates that *ck*/myoVIIA functions to organize the auditory organ, that is, it is functionally required in neuronal and support cells, but that it is not required for TRPV channel localization or for scolopidial-cell-junction integrity. Conditional mutations of MyoVIIa are needed to establish adult function of MyoVIIa beyond that obvious developmental function. Only conditional adult null flies could show whether *ck* is also involved in intracellular tethering, comparable to functions suggested for mammals (Gillespie, P. G. *et al.*, 2005; Senften, M. *et al.*, 2006).

Flies also have multiple members of the DEG/ENaC family. One member of that gene family, pickpocket (*ppk*), has been implicated in mechanotransduction in larvae (Ainsley, J. A. *et al.*, 2003), and their presumptive role in adult cuticular mechanotransduction has not been tested (Lumpkin, E. A. and Bautista, D. M. 2005). Clearly, more DEG/ENaC genes have to be mutated alone, or in combination, before their involvement in mechanotransduction can be verified. For flies and nematodes it appears that both TRP and DEG/ENaC channels are involved in mechanosensation without clear correlation of either channel with specific receptor configurations (Goodman, M. B. *et al.*, 2002; Goodman, M. B. *et al.*, 2004; Hilliard, M. A. *et al.*, 2005; Li, W. *et al.*, 2006).

3.05.3 Mechanosensory Cells in Vertebrates

All vertebrates have placodally derived hair cells that mediate mechanotransduction in the lateral line (if present) and the inner ear (Lewis, E. R. *et al.*, 1985). Hair cells have been claimed to be "probably the most elegant solution for stimulus delivery" (Sukharev, S. and Corey, D. P., 2004). Mechanotransduction requires deflection of stiff actin-rich microvilli (called stereocilia), connected by tip links, and thus opening mechanotransducing channels located at the tips of stereocilia (Lewis, E. R. *et al.*, 1985; Hudspeth, A. J., 1989). With respect to overall organization, a hair cell with stereocilia and the eccentrically positioned kinocilium can be interpreted as a transformation of the ancestral mechanosensory cell (Figure 4) found in other deuterostomes, coelenterates, and even some single-celled organisms (Jorgensen, J. M., 1989; Fritzsch, B. *et al.*, 2006a). During development, hair cells start with microvilli surrounding a central kinocilium that eventually moves into an eccentric position under the influence of cell-polarizing signals (Barald, K. F. and Kelley, M. W., 2004). At the end of the differentiation process, an organ pipe distribution of the stereocilia is established with the kinocilium, being eccentric on one side of the cell or being lost in mammalian cochlear hair cells (Bryant, J. E. *et al.*, 2005). Below, we will highlight some genes found to play roles in the development and structural maturation of the hair cell apex.

Placodes produce not only the ear and the lateral line but also essential components of all head sensory systems (Schlosser, G., 2005). The so-called dorsolateral set of placodes produces not only the hair cells and the sensory neurons of the ear and the lateral line system of organs but also the electroreceptive hair cells and sensory neurons of ampullary electroreceptors (Northcutt, R. G. *et al.*, 1995). Given the polymodal nature of putative mechanosensory channels, it is possible that the still-unknown electrosensory channel or channels in electroreceptors of ampullary and tuberous organs (Bullock, T. H. and Heiligenberg, W., 1986) might have evolved from a mechanically gated channel that has lost its tethers.

As already introduced above, terrestrial vertebrates have numerous free and specialized nerve endings that respond to stretch or shearing forces, such as Pacinian corpuscles, Ruffini endings, Merkel cells, and muscle spindles. Since these structures are clearly derived features of terrestrial vertebrates they

cannot illustrate the early evolution of mechanosensory cells and the appropriate mechanosensory hair cell channel in vertebrate ancestors. We therefore do not consider most of those cells and concentrate on only one additional mechanosensory cell of vertebrates, the Merkel cell.

Like hair cells, which are the ancestral mechanosensory cell of vertebrates based on outgroup comparisons with invertebrates (Figure 4), Merkel cells have numerous microvilli extending, however, between the ectodermal cells that surround them rather then into the endolymph of the inner ear or into water (lateral line). Recent evidence suggests that the Merkel cell has the molecular machinery for synaptic transmission, thus likely representing a mechanosensory cell in its own right (Haeberle, H. *et al.*, 2004). However, Merkel cell afferent fibers also show the presence of DEG/ENaC proteins (Price, M. P. *et al.*, 2000). Most importantly, several genes relevant for hair cell differentiation are also expressed in developing Merkel cells (Bermingham, N. A. *et al.*, 1999; Leonard, J. H. *et al.*, 2002; Wallis, D. *et al.*, 2003). In contrast to hair cells, Merkel cells derive from the neural crest (Szeder, V. *et al.*, 2003) and Merkel cells are a source of stem cells that can turn carcinogenic, in particular in mutations of genes critical for differentiation of hair cells and Merkel cells (Leonard, J. H. *et al.*, 2002). Whether the mechanosensory channels of Merkel cells and hair cells are identical, as is possible based on detailed transcription factor identity, or are different based on the different embryonic origin, remains to be seen.

In summary, outgroup comparison indicates that the vertebrate hair cell represents many of the basic features also found in distantly related putative mechanosensory cells of nonecdysozoan invertebrates (Figure 4). The basic feature of the mechanotransduction apparatus of the vertebrate hair cell is the 20–300 stereocilia (modified microvilli with a dense actin core) organized in increasingly taller rows toward the kinocilium. Typically, a bundle of stereocilia with variable length is grouped adjacent to the single kinocilium. Stereocilia are interconnected with tip and other links, presumably providing directional sensitivity to stimuli and bundle integrity. Vestibular hair cells of vertebrates show a great many variations in the lengths of kinocilium and stereocilia and number of stereocilia (Lewis, E. R. *et al.*, 1985; Bryant, J. E. *et al.*, 2005). Similar features characterize the lateral line hair cell that derives from placodes adjacent to the ear placode.

3.05.3.1 The Zebrafish *NompC (TRPN-1)*: Is There a Divergent Base for Mechanosensory Transduction in the Apparently Structurally Conserved Vertebrate Hair Cells?

Mutagenetic studies of zebrafish have identified a number of animals that are defective in gravity, lateral line, and touch reception. The mutations underlying several of these defects have been cloned and their molecular basis has been identified (Ernstrom, G. G. and Chalfie, M., 2002; Syntichaki, P. and Tavernarakis, N., 2004; Nicolson, T., 2005). Most interesting is the finding that a zebrafish *nompC* ortholog apparently has defects in hair cell mechanotransduction (Sidi, S. *et al.*, 2003; Nicolson, T., 2005), suggesting that this TRPN molecule is a part of the channel complex. No data narrowing down the anatomical localization of the NOMPC protein exist in zebrafish. However, a frog TRPN-like gene with limited sequence similarity was recently cloned and antibodies were raised against the protein (Shin, J. B. *et al.*, 2005). The data suggest that the frog TRPN-like protein is associated with the kinocilium in hair cells and other epidermal cells. This essentially rules this gene out as a candidate for mechanosensory transduction in stereocilia (Hudspeth, A. J., 2005). What function TRPN plays in zebrafish hair cell mechanotransduction is at the moment unclear. Minimally, a conditional analysis needs to be performed to rule out that the apparent defects are not mediated by an as yet unknown crucial developmental function, analogous to the needed functional verification of MyoVIIa. In addition, screening of mouse and human genomes could not identify a TRPN gene ortholog (Goodman, M. B. *et al.*, 2004; Gillespie, P. G. *et al.*, 2005; Lin, S. Y. and Corey, D. P., 2005). Obviously, whatever function is performed by the TRPN in zebrafish is dispensable for mammalian hair cells and may be unique to zebrafish and other related teleosts. More needs to be known about the distribution of *nompC*-like genes in bony fish (teleosts?) before any detailed hypothesis about the significance of the zebrafish finding can be expanded to other bony fish.

These data highlight the strength but also the risk of a mutagenic approach: it can identify a candidate gene, but requires additional work to put the apparent functional defects into the context of known mechanotransduction data. In this context, several candidate genes of the TRPV and TRPA families have been identified in mammals. However, null mutants of each showed no effects, indicating that

those TRP genes, despite being expressed in hair cells, are not essential for mechanotransduction. Of note, the TRPA1 channel that was recently discussed as a potential candidate for the mammalian mechanosensory channel (Corey, D. P. *et al.*, 2004) has recently been knocked out and shown to mediate, as expected based on comparative data (Goodman, M. B. *et al.*, 2004; Tobin, D. M. and Bargmann, C. I., 2004), not mechanotransduction, but rather sensitivity to mechanical, chemical, and cold stimuli in nociceptors in various dorsal root ganglion neurons and hair cells (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006). The expression of *Trpa1* in ganglion neurons seems to be regulated by *Runx1* (Chen, C. L. *et al.*, 2006), a transcription factor that has not been identified in ear development.

3.05.3.2 The Mammalian Cochlear Hair Cell: Adapting an Ancestral Cell to Very High Frequencies

In contrast to the evolutionarily stable bundle configuration of vestibular hair cells, mammalian hair cell stereocilia show some derived features. First, mammalian auditory hair cells lose the kinocilium in neonates, signifying that this structure is functionally dispensable. In addition, the three rows of outer hair cells (OHCs) display a W-organization of stereocilia whereas the single row of inner hair cells displays a C-shaped bundle showing the greatest bundle differences in a single epithelium. Among vertebrate hair cells, mammalian outer and, to a lesser extent, inner hair cells are the most derived with respect to bundle organization. How these changes relate to the much expanded high-frequency hearing range of mammals, which can exceed 100 kHz, is unknown.

Much has been learned about the molecular organization of stereocilia. Obviously, the central role of shearing motion detection requires that stereocilia behave as stiff rods that slide along each other as the bundle is deflected in a specific direction. If deflection is in the direction of the kinocilium, the bundle sliding results in increased or reduced tension of the tip links, thereby opening still unknown cation channels that allow endolymphatic potassium to enter the hair cell and change its membrane potential. Many mutations have been identified in hair cell actin organization or in molecules suspected as functional components of the transduction apparatus (Table 2), and their molecular interactions, while not yet completely understood, have begun to emerge (Bryant, J. E. *et al.*, 2005; Ahmed, Z. M. *et al.*, 2006; Senften, M. *et al.*, 2006). Actin and several associated proteins that ensure the stability of the actin core are essential for the normal function of any hair cell by providing the stiff core of the stereocilia (Figure 5). Connecting and maintaining actin filaments is provided by various proteins such as *fimbrin*, *t-plastin*, and *espin*. Growth and anchoring of the actin filaments to the membrane is further ensured by additional proteins such as *whirlin* and several rare *myosins*, in particular MyoVI and MyoXV, to the cuticular plate and the tip of the stereocilia, respectively (Bryant, J. E. *et al.*, 2005). Ankle links near the base of stereocilia appear to be formed by *MyoVIIa*, *verzatin*, and an as yet uncharacterized ankle link antigen. *Protocadherin* 15 may participate in this complex or may participate in the tip link connections (Bryant, J. E. *et al.*, 2005; Gillespie, P. G. *et al.*, 2005; Ahmed, Z. M. *et al.*, 2006). The tip link complex is currently speculated to be composed of *Cadherin 23*, *Harmonin b*, *Protocadherin 15*, *Myo VIIa* (at least during development), and *Myo 1b* (Figure 5). Mutations of several of these genes affect either bundle formation or bundle cohesion, leaving them split open instead of tied together. No matter what aberration in bundle appearance is introduced by mutation, hearing is typically lost, demonstrating bundle integrity as a major component of mechanotransduction (Hertzano, R. and Avraham, K. B., 2005). These data show, even in the absence of molecular identification of the mechanotransducer channel, that both intracellular connections and stereocilia connections are essential for auditory sensitivity (Hudspeth, A. J., 2005). Insects have also evolved active mechanisms to amplify low-intensity auditory stimuli. Mosquito and fruit fly antennae (Johnston's organs) are excellent examples (Gopfert, M. C. and Robert, D., 2001).

3.05.3.3 Active Processes in Hair Cells

Unlike any other known sensory receptor, hair cells have found a way – perhaps more than one – to overcome the effect of viscous damping from the fluid in which they immerse. They have developed an active process, a motor for the mechanical amplification of low-intensity stimuli. By imparting mechanical energy to a hair bundle, this amplificatory process partly counters the loss of energy through viscous drag. This process evolved at least 380 million years ago, for it is employed by amphibians, reptiles, and birds, as well as by mammals. Fish

Table 2 Partial list of mutations in nematodes and mice that affect mechanosensation

					MyoIc	Adaptor for channel?	?

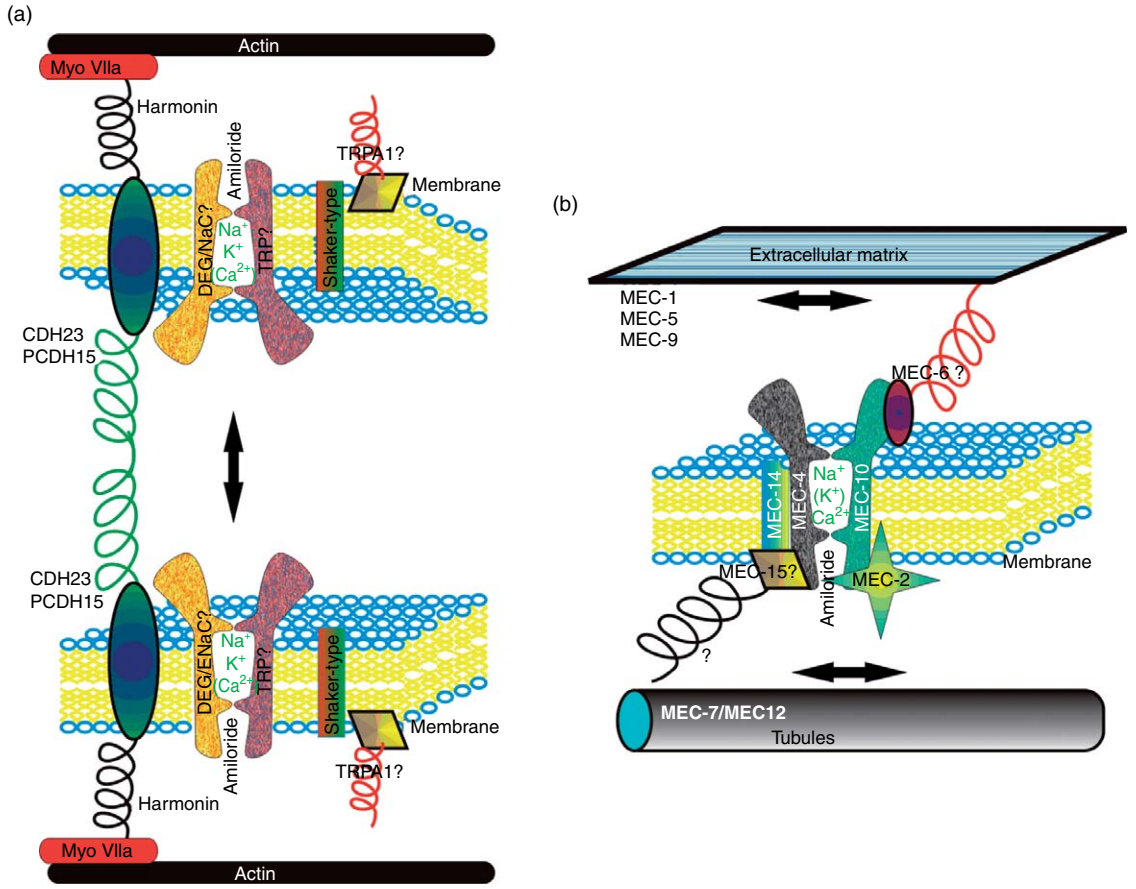

Figure 5 The basic organization of the mechanosensory channel of a vertebrate hair cell (a) and a nematode fine-touch sensor (b) are compared. Mutations analysis has identified several genes that are essential for the function in either taxon. In nematodes, fine touch is lost when either specific molecules of the extracellular matrix to which the channel is anchored are lost (Mec-1,5,9) or if specific components of the channel complex are lost (Mec-2,4,10,14). However, loss to the intracellular tubules (Mec-7, 12) may lead only to a reduced sensitivity, not a complete loss of sensation. In contrast, in vertebrates there is no extracellular matrix or cuticula connection. Instead, two stereocilia are interconnected presumably by Cdh23 that is hypothesized to be anchored to MyoVIIa via harmonin. Loss of any of these genes results in deafness indicating that in vertebrates mechanosensation requires relative movement against the actin core of the stereocilia. Additional connections exist between Cdh23 and Myo1c but no knockout data support the claimed function as an adaptor. It is speculated that MyoVIIa transports the still unknown amiloride-sensitive mechanosensory channel to the tip, but it is unclear whether this connection remains past development. In nematodes, at least two essential subunits of the DEG/ENaC channel are known whereas it is not clear whether the vertebrate channel is composed of DEG/ENaC or TRP channels. Certain candidates have been excluded as mutants in, for example, TRPA1 do hear excluding an essential role of this protein in mechanosensory transduction. Note that both nematode and vertebrate have a shaker-type channel associated with the mechanosensory channel, but details are unknown. Adapted from (Bryant, J.E., Forge, A., and Richardson, G.P. 2005. The Differentiation of Hair Cells. In: Development of the Inner Ear (*eds.* M.W. Kelley, D.K. Wu, A.N. Popper, R.R. Fay,), pp. 158–204. Springer. and O'Hagan, R., Chalfie, M., Goodman, M.B. 2005. The MEC-4 DEG/ENaC channel of *Caenorhabditis elegans* touch receptor neurons transduces mechanical signals. *Nat. Neurosci.* 8, 43–50.

ears too may well display mechanical amplification, which, like the structure of the hair cell, may prove to be a general feature of vertebrates.

Two mechanisms of active amplification have been proposed. In the mammalian cochlea, OHCs function as the key elements in a mechanical feedback loop in which the fast somatic motility of OHCs is thought to be the source of cochlear amplification. An alternative view is that amplification arises from active hair-bundle movements, similar to that seen in nonmammalian hair cells (Zheng, J. *et al.*, 2000; Hudspeth, A. J., 2005; Dallos, P. *et al.*, 2006). Although these mechanisms have been proposed, and evidence has been garnered in support of each,

there is no receptor organ in which the mechanism is unequivocally known. However, the strongest candidate to explain amplification in the mammalian cochlea is unlikely to operate in the receptor organs of amphibians, reptiles, or birds (He, D. Z. *et al.*, 2003).

The OHC of the mammalian cochlea functions not just as a receptor cell but, more importantly, as an effector. OHCs can convert voltage stimulation, the receptor potential, into somatic length change (Brownell, W. E. *et al.*, 1985; Kachar, B. *et al.*, 1986). Such electromechanical or reverse transduction can operate at high frequencies (Dallos, P. and Evans, B. N., 1995). The gene named *prestin* that codes the membrane-bound motor protein was identified (Zheng, J. *et al.*, 2000). Prestin belongs to a distinct anion transporter family called solute carrier protein 26 (SLC26) (Zheng, J. *et al.*, 2002). At present, 11 members of this family have been identified (Mount, D. B. and Romero, M. F., 2004). Several proteins in this family, including prestin, are involved in human diseases (Dawson, P. A. and Markovich, D., 2005). The human Prestin gene contains 21 exons crossing more than 90 kb in chromosome 7q22 (Liu, X. Z. *et al.*, 2003), a location near to those of other important SLC26 members, such as PDS (SLC26A4) (Everett, L. A. *et al.*, 1997) and DRA (SLC26A3) (Haila, S. *et al.*, 1998). The mouse Prestin gene has 20 exons spanning nearly 55 kb in chromosome 5 (Zheng, J. *et al.*, 2003). Eighteen of these exons code for prestin amino acids in both hPrestin and mPrestin. Among coding exons, 12 exons are exactly the same sizes as in other members of the SLC26 family, such as Pendrin, DRA, and CFEX (Zheng, J. *et al.*, 2003), indicating a high likelihood for homology among these genes. Several prestin isoforms have also been found in different stages of human cochlear development (Liu, X. Z. *et al.*, 2003).

Amphibian and reptilian ears are also sensitive and sharply tuned and produce otoacoustic emissions despite the fact that they lack OHCs (van Dijk, P. and Manley, G. A., 2001; Manley, G. A., 2001). This is consistent with a cochlear amplifier in which the stereocilia not only act as a receptor organelle, but also act as a force-generator (Hudspeth, A., 1997; Fettiplace, R. and Hackney, C. M., 2006). Indeed, active hair-bundle motion has been observed in hair cells of turtles and bullfrogs as reactions to hair-bundle displacement with compliant probes, and in response to changes in membrane potential. The active hair-bundle movements intimately related to the reclosure of the mechanotransducer channels and the myosin motors involved in adaptation can produce forces that amplify mechanical stimuli. The movements are sensitive to extracellular calcium concentration and can be altered by calcium influx through the mechanoelectrical transducer channels. However, the molecular basis of this active process is still unclear.

3.05.3.4 Development of Mechanoreceptor Cells: Molecular Transformation of an Epidermal Cell into a Mechanoreceptor

Numerous genes that appear to be essential for hair cell development in vertebrates and in Johnston's organs alike have been identified (Caldwell, J. C. and Eberl, D. F., 2002; Dong, P. D. *et al.*, 2003; Fritzsch, B. and Beisel, K. W. 2004; Boekhoff-Falk, 2005; Todi, S. V. *et al.*, 2005). Expanding this comparison to *C. elegans* allows a set of conclusions to be drawn about the stereotyped events that happen during mechanosensory organ development (Table 3). First, organ precursors have to be selected from ectoderm and turned into precursor cells able to respond to genes that initiate their differentiation. Such genes belong to

the PAX domain factors (*Pax2*, *Dpax-2*) in vertebrates and in *D. melanogaster*. Other factors that have been specified in placodal induction belong to the *Wnt* and *Shh* genes, and these important diffusible morphogens likely also play a role in fly and nematode development. In vertebrates, several genes are necessary for the overall differentiation of the auditory organ or the ear, such as *Eya1*, *Gata3*, and *Sall/spalt*. Spalt-like transcription factors also contribute to touch cell fate in nematodes (Toker, A. S. *et al.*, 2003) and flies (Dong, P. D. *et al.*, 2003). Later expressed factors are essential for hair cell differentiation, such as the bHLH gene *Atoh1/atonal* of vertebrates and flies and the unrelated bHLH gene *lin-32* in nematodes. bHLH genes interact with POU domain and zinc finger genes to ensure proper differentiation of vertebrate hair cells and chordotonal organs alike. The latter genes are also found in diploblasts, suggesting that some developmental aspects of mechanosensory cell- and organ-specific transcription factors are conserved (Fritzsch, B. *et al.*, 2006a), even in the presence of the highly divergent morphology of such cells. In addition, the proper differentiation of hair cell and chordotonal transducer organs depends critically on several unconventional myosins, some of which are shared between flies and mice (Table 3) and are known already in the protist ancestors of multicellular organisms. It thus appears possible that development of mechanosensory cells may present a variation of a scheme already present in diploblasts and conserved in the molecular interactions, if not the molecules involved, across triploblast phyla. In simple terms, we can view these developmental transcription factors as conductors that orchestrate somehow the assembly of a molecular complex necessary for the mechanotransduction via a tethered mechanosensory channel to work. Unfortunately, how these transcription factors regulate the extra- and intracellular matrix development and the expression of mechanosensory channels and their tethering molecules is unknown at the moment.

3.05.4 Conclusions

Analyses of mutations in nematodes, flies, zebrafish, and mammals have identified a number of genes whose products play a role in mechanosensory function and development. However, only in nematodes do we have enough components of the transduction complex identified that we can begin to model the function of those proteins. The basic components are the channel, composed of at least two subunits, and an attachment to the cuticle. An intracellular attachment, previously deemed essential (Ernstrom, G. G. and Chalfie, M., 2002), is needed only for increased sensitivity of sensation (O'Hagan, R. *et al.*, 2005). Other animals such as zebrafish and mammals show sensitivity reduction or loss after mutations in over 100 genes, suggesting that the transduction complex requires more components for proper function, perhaps including a more sophisticated developmental regulation. Neither the detailed organization of the channel complex nor its connection to intra- and extracellular tethers is sufficiently known to explain the gating properties and its ability to follow repetitive stimuli to high frequencies.

Clearly, the past approach of unraveling the genetic basis of mechanosensory cell development and function by mutational analysis has been successful in identifying several genes necessary for proper development and/or function. The plethora of unsuccessful mutations in vertebrates that failed to demonstrate the mechanosensory function of a given gene because of limited viability, additional involvement in development, or absence of a phenotype perhaps related to redundancy suggest that it is may be time to alter our strategy. Single mutations assume that a given gene cannot be replaced by other genes (lack of functional redundancy). They further assume that the loss of function is associated only with adult mechanotransduction. Both of these assumptions may be untrue, and animals may not even mature in the absence of specific genes such as β-ENac (early lethal), or may not properly differentiate (MyoVIIa). In addition, while MEC-4 and -10 are different enough to be functionally distinct and cannot be substituted by each other, this may not be the case for all components of the possibly heteromultimeric vertebrate mechanotransducer channels.

Further progress requires the implementation of better strategies. Recently, mice were generated with hair cell-specific *Cre* expression (Matei, V. *et al.*, 2005; Tian, Y. *et al.*, 2006). Such mice could be crossed with mice in which all genes of a given family are floxed and can therefore be all eliminated at the same adult stage, simply by delayed activation of the hair cell-specific *Cre*. Once specific effects have been found, mice can be generated in which more and more of the putative channels are expressed. This way the relevant combination of genes necessary for proper function could be established. Ultimately, ear-specific conditional deletions of one or more of these genes, combined with the hair cell-targeted expression of

these genes, needs to be performed to verify that they are not only necessary but also sufficient. The way ahead therefore requires more work to generate floxed genes, clearly an effort that requires collaboration between multiple laboratories.

Analysis of mechanosensation has been a difficult road. What we learned thus far is that many channels can respond to mechanical force, albeit not with the high sensitivity of channels now considered to be dedicated to mechanosensation. In the absence of a clear-cut molecular definition of mechanosensory channels across phyla, we can only deal with an operational definition of a mechanosensitive cell to guide future research:

A mechanosensory channel responds maximally to low-intensity mechanical forces of a few micronewtons to piconewtons with a rapidly activating (pS), nondesensitizing, increased conductance. Such a channel will respond to membrane stretch (nontethered) or pull on extra- or intracellular attachments (tethered channels).

3.05.5 Note Added in Proof

Two recent papers have direct bearing for the review (Christensen, A. P. and Corey, D. P., 2007; Vollrath, M. A. *et al*., 2007). In addition, a recent paper established that coelenterates and deuterostomes show more genetic similarities with each other than either has with protostomes, essentially what we proposed based on the similarities in apical mechanosensory specializations (Putnam, N. H. *et al*., 2007).

Acknowledgments

This work was supported by NIH (DC005590) and a grant from Dr. Richard Bellucci. This investigation was conducted in a facility constructed with support from Research Facilities Improvement Program Grant Number 1 C06 RR17417-01 from the National Center for Research Resources, National Institutes of Health. We acknowledge the use of the confocal microscope facility of the NCCB, supported by EPSCoR EPS-0346476 (CFD 47.076). We would like to express our gratitude to Drs. Miriam B. Goodman and Dan Eberl for helpful insights and discussion that helped fine-tune this review. However, the perspective and views expressed are only those of the authors.

Glossary

acousticolateralis system The system of organs associated with hearing, balance, and the lateral line (see sacculus).

BAPTA A specific calcium ion chelator (1,2-bis(*o*-aminophenoxy)ethane-*N*,*N*,*N*′,*N*′-tetraacetic acid) used to reduce or eliminate free calcium from a solution.

basilar membrane Tough fibrous membrane on which the organ of Corti sits and which forms the lower border of the cochlear duct.

cochlear amplifier Biophysical mechanism within the cochlea that enhances frequency selectivity and sensitivity.

cochlear duct Triangular chamber running longitudinally through the cochlear spiral and containing the organ of Corti.

cochleotopic Gradients that vary systematically along the cochlea.

cuticular plate An apical mat of cytoskeletal proteins in hair cells that supports the hair bundle (see cytoskeleton).

cytoskeleton Network of various kinds of filament and associated molecules that provide mechanical support, movement, and transport processes within cells.

electromotile Electrically induced cellular motility, usually used to describe outer hair cell somatic motility.

endocochlear potential Extracellular electrical potential in the cochlea generated by the lateral wall of the cochlear duct.

endolymph The fluid in the scala media, composed of a high concentration of potassium ions and low concentrations of other ions.

en passant Synapses formed in passing between two neural processes or nerve cells.

eukaryote Organism whose cells contain a membrane-bound, structurally discrete nucleus and other subcellular compartments.

freeze-fracture A technique of electron microscopy where tissue is broken open in a way that cleaves cell membranes along their central lipid bilayer to reveal the intrinsic membrane particles.

gap junctions Junctions between cells formed from arrays of proteins called connexons that cross a narrowed intercellular space and form pores that allow direct transfer of ions and small molecules between the cells.

immunocytochemical labeling (immunocytochemistry) A technique for specific labeling of proteins or particular regions of a protein molecule using antibodies.

ionotropic receptor A class of neurotransmitter receptor that is also an ion channel and exerts its effects via ionic currents into the stimulated cell (see metabotropic receptor).

isoform A subtype of a particular protein, displaying small differences in structure and properties.
junctional complex A region of junctions of several different types between cells.
kinocilium A subcellular protrusion, similar in external appearance to a stereocilium but based on an axoneme composed of microtubules, typical in structure to cilia from many other parts of the body (see stereocilium).
mechanoelectrical transduction Conversion of mechanical stimulus energy to electrical potentials.
membraneous cisternae Layers of membrane beneath the surfaces and in the cytoplasm of cells.
metabotropic receptor A class of neurotransmitter receptor molecule that exerts its effects via second messenger systems in the stimulated cell (see ionotropic receptor).
modiolus Central bony pillar of the cochlea.
orthologue A gene sequence of another species that shares a direct common ancestor with the species being considered.
paracrystalline A crystalline-like arrangement of filaments in an actin bundle.
perilymph The fluid in the scala vestibuli and scala tympani, containing principally sodium ions and with substantially lower concentrations of other ions.
permeant blocker An ion or small molecule that can pass through an ion channel but also blocks it and prevents other ions/molecules passing through.
prokaryote Cell or organism such as a bacterium that lacks a membrane-bound, structurally discrete nucleus and other subcellular compartments.
resting potential The membrane potential of an unstimulated sensory receptor.
reticular lamina Upper surface of the organ of Corti, consisting of the adjacent apices of hair cells and supporting cells.
sacculus One of the otolithic organs of the inner ear, associated with balance.
scala media Central compartment of the cochlear duct, containing endolymph.
scala tympani Longitudinal compartment running below the basilar membrane of the cochlear duct, containing perilymph.
scala vestibuli Longitudinal compartment running above Reissner's membrane of the cochlear duct, containing perilymph.
spiral ligament Structure containing fibrocytes and extracellular matrix which together with the stria vascularis forms the lateral wall of the cochlear duct.
stereocilia Hair-like subcellular protrusions similar in structure to microvilli but much larger, forming the characteristic cluster of hairs (the hair bundle) on the apex of the hair cell that contains the sensory apparatus (see kinocilium).
stria vascularis Vascular epithelium containing the blood vessel of the lateral wall of the cochlear duct.
tectorial membrane Fibrous flap of extracellular matrix overlying the organ of Corti, which is part of the structure that delivers the mechanical stimulus to the hair cells.
transgenic An animal that has been derived from genetically modified sperm or egg cells.

3.06.1 Introduction

The sensory cells of the auditory organs of vertebrates, the hair cells, are mechanosensory receptors that are adapted to detect minute mechanical stimuli. The receptor cell relies for this sensitivity on a cluster of organelles that project from its apex, the subcellular protrusions or hairs (stereocilia) which give the hair cell its name. Similar receptors are also found in vestibular organs where they are associated with the sense of balance and in the lateral line systems of fish and amphibians where they detect water movements. There are fundamental features shared by all hair cells that suggest that there is a common mechanism of mechanotransduction, the process by which they convert a mechanical stimulus into an electrical response that results in neurotransmission, the process by which their electrical response is sent to the brain. However, hair cells with varying morphologies and fine structure can be found, both within a single auditory or vestibular sensory epithelium and between sensory organs of

different vertebrate classes (see review by Furness, D. N. and Hackney, C. M., 2006). The hair cells are surrounded by supporting cells which also vary in morphology and organization, both in different epithelia and within an epithelium.

The cochlear hair cells and the supporting cells and other structures around them contain some molecules that are common to the equivalent cells in all auditory organs, and some that may be unique to a particular hair-cell or supporting-cell type or organ, either associated with distinct functional differences or performing an analogous role. The situation is further complicated by the fact that some molecules may have been described in certain tissues and hair-cell types but not in others, not necessarily because they are absent but because an appropriate method, molecular probe or genetic model, is not available or because the relevant investigation has not yet been done.

The purpose of this chapter is to review the molecular composition of hair cells and supporting cells determined from studies of a range of different hair-cell epithelia, including both vestibular and auditory organs, with the emphasis on the mammalian organ of Corti. These studies include genetic analysis of deafness genes (see Perspective a), molecular biological and immunohistochemical analysis of gene expression, electrophysiology and pharmacology, and correlated structural studies. Different molecules appear at different developmental stages, so account needs also to be taken of the age of the organisms studied. In general, this chapter will not consider developmental regulators or other factors that may play a transient role in the construction of the sensory epithelium but concentrate for the most part on molecules associated with its adult functional properties.

3.06.1.1 Basic Anatomy of Auditory Epithelia and the Hair Cells

The auditory organ of mammals is the cochlea, a snail-shell shaped part of the bony labyrinth of the inner ear lined by membranes and containing the membraneous cochlear duct. The sensory epithelium, the organ of Corti, is found within the cochlear duct (Figure 1). The epithelium is situated on the basilar membrane which forms the lower margin of the duct. This structure is composed of tough extracellular matrix molecules such as type IV collagen (Cosgrove, D. *et al.*, 1996a; 1996b), type II collagen, fibronectin, tenascin, 4S/6S chondroitin sulfate proteoglycans, decorin, αV and β1 integrins (Tsuprun, V. and Santi, P., 1999), emilin (Amma, L. L. *et al.*, 2003), and mainly laminin type 11 (Rodgers, K. D. *et al.*, 2001), the latter probably being located in the basement membrane which lies between the organ of Corti cells and the basilar membrane. Overlying the epithelium is a gelatinous flap, the tectorial membrane composed of collagen types II, V, and IX (Slepecky, N. B. *et al.*, 1992), with additional unique glycoproteins, α- and β-tectorin (Legan, P. K. *et al.*, 1997). The tectorial membrane is attached to the modiolar side of the cochlea (see below and Figure 1) where it arises from a ridge of tissue, the spiral limbus. The lateral wall of the cochlear duct stretches up from the outer edge of the basilar membrane inside the bony outer shell of the cochlea. It contains the stria vascularis, an epithelium composed of three layers of cells involved in homeostatic mechanisms that control the ionic balances of cochlear fluids, external to which is the spiral ligament that is composed mainly of extracellular material and fibrocytes (see, e.g., Spicer, S. S. and Schulte, B. A., 1991). A third membrane, Reissner's membrane that has two layers of cells, attaches the stria vascularis to the inner edge of the organ of Corti making the duct triangular in cross section (Figure 1). The central compartment of the duct, the scala media, is chemically and electrically isolated from the compartments above (the scala vestibuli) and below (scala tympani) by means of tight junctions connecting all of the cells that compose the inner lining. This allows a high potassium and low sodium content to be maintained in the fluid in the duct (endolymph) compared with fluid in the other scalae (perilymph), the latter being more typical of an extracellular solution as it is high in sodium (Konishi, T. and Salt, A. N., 1980). Various ion pumps and transport mechanisms situated in the lateral wall maintain the electrical potential of the scala media at around +80 mV compared with 0 mV in perilymph and negative potentials of the hair cells. The resultant endocochlear potential (EP) is vital for the maintenance of cochlear sensitivity as it provides a battery that powers both the mechanoelectrical and electromechanical properties crucial to normal hearing (see, e.g., Kirk, D. L. and Yates, G. K., 1998). Consequently, failure of the homeostatic mechanisms that generate and maintain the EP can result in impairment and loss of hearing (see Perspective b) and is potentially involved in Ménière's disease (see Perspective c).

The cochlear duct winds spirally around a central bony pillar, the modiolus (Figure 1), within which is the spiral ganglion of the auditory nerve. Peripheral processes of the spiral ganglion neurons emerge from the modiolus and innervate the hair cell via the

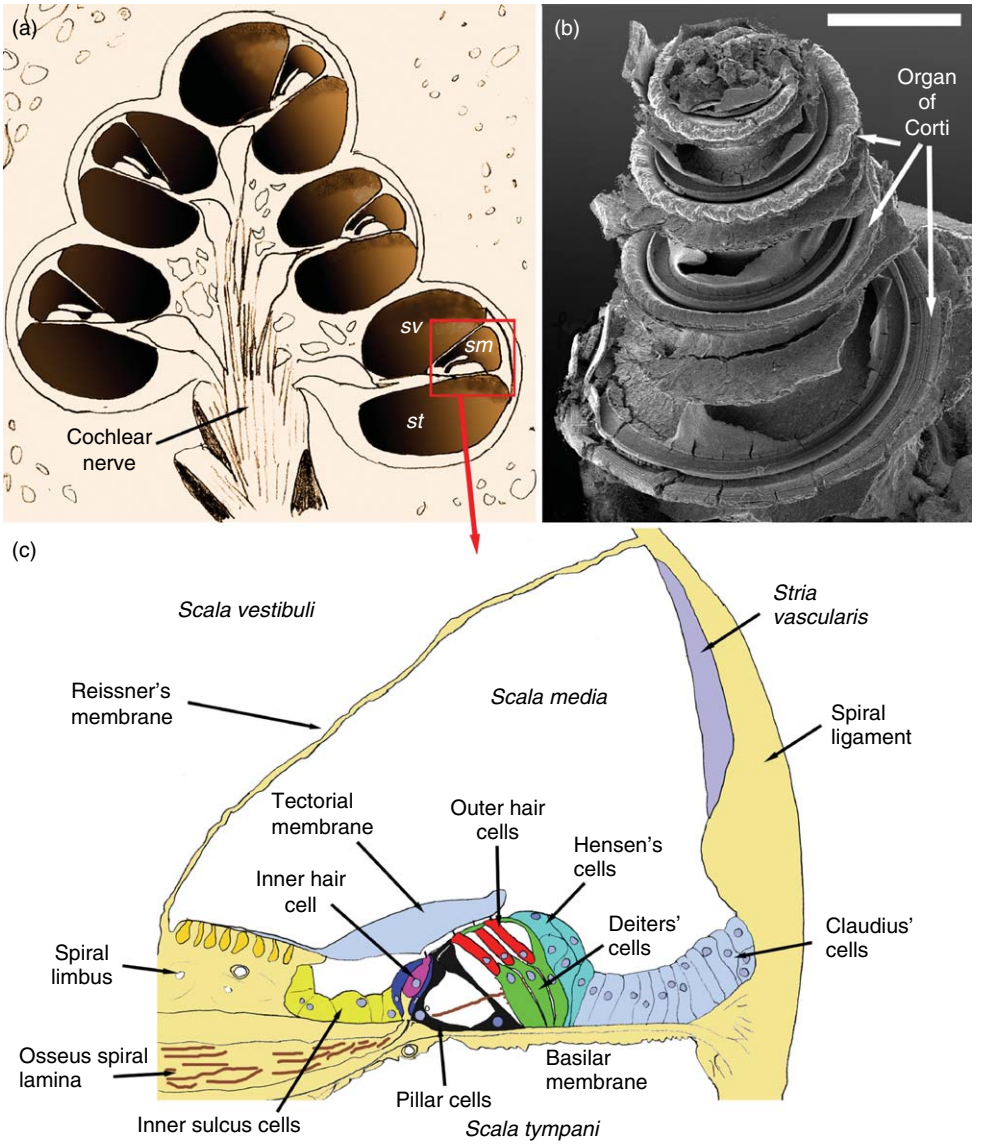

Figure 1 Gross anatomy of the cochlea and cytoarchitecture of the organ of Corti. (a) Diagrammatic cross section of a mammalian cochlea which consists of a canal that spirals around a central bony pillar, the modiolus, which contains the cochlear nerve. The canal is subdivided longitudinally by the central cochlear duct the scala media (*sm*), containing the organ of Corti, the scala vestibuli (*sv*) above and the scala tympani (*st*) below. (b) Scanning electron micrograph of a guinea pig cochlea dissected to reveal the organ of Corti. Scale bar = 0.5 mm. (c) Diagram of a cross section showing the scala media (the region enclosed by the red box in (a). The three boundaries are Reissner's membrane with scala vestibuli above, the lateral wall (composed of the stria vascularis and spiral ligament), and basilar membrane with scala tympani below. The organ of Corti sits on the basilar membrane and contains the inner and outer hair cells and supporting cells. The latter include the pillar cells and the Deiters' cells which support the outer hair cells and the Hensen's cells which are on the strial edge of the sensory epithelium. Other cells bordering the epithelium are, on the strial side, Claudius' cells and, on the modiolar side, the inner sulcal cells. The tectorial membrane is in contact with the tips of the hairs of the OHCs and is hinged along the spiral limbus. The innervation of the hair cells enters the organ of Corti via perforations in a bony shelf, the osseous spiral lamina.

osseous spiral lamina. Central processes of these neurons project to the cochlear nuclear complex. The cochlea is also innervated by efferent nerve fibers which predominantly originate in the superior olivary complex from neurones located both ipsilaterally in the lateral superior olivary nucleus (the lateral system) and contralaterally in the medial superior olivary nucleus (the crossed olivocochlear system).

The organ of Corti is composed of hair cells and supporting cells organized in a precise geometric array. Hair cells are of two types, inner hair cells (IHCs) forming one row along the cochlear spiral and consisting of flask-shaped cells with a more or less linear longitudinal (with respect to the direction of the spiral) array of stereocilia along their apices and three rows of outer hair cells (OHCs) with cylindrical cell bodies and an apical W-shaped bundle of stereocilia (Figure 2). In adults, the hair bundles are composed of around 50 stereocilia in IHCs and 90 in OHCs, although the precise number

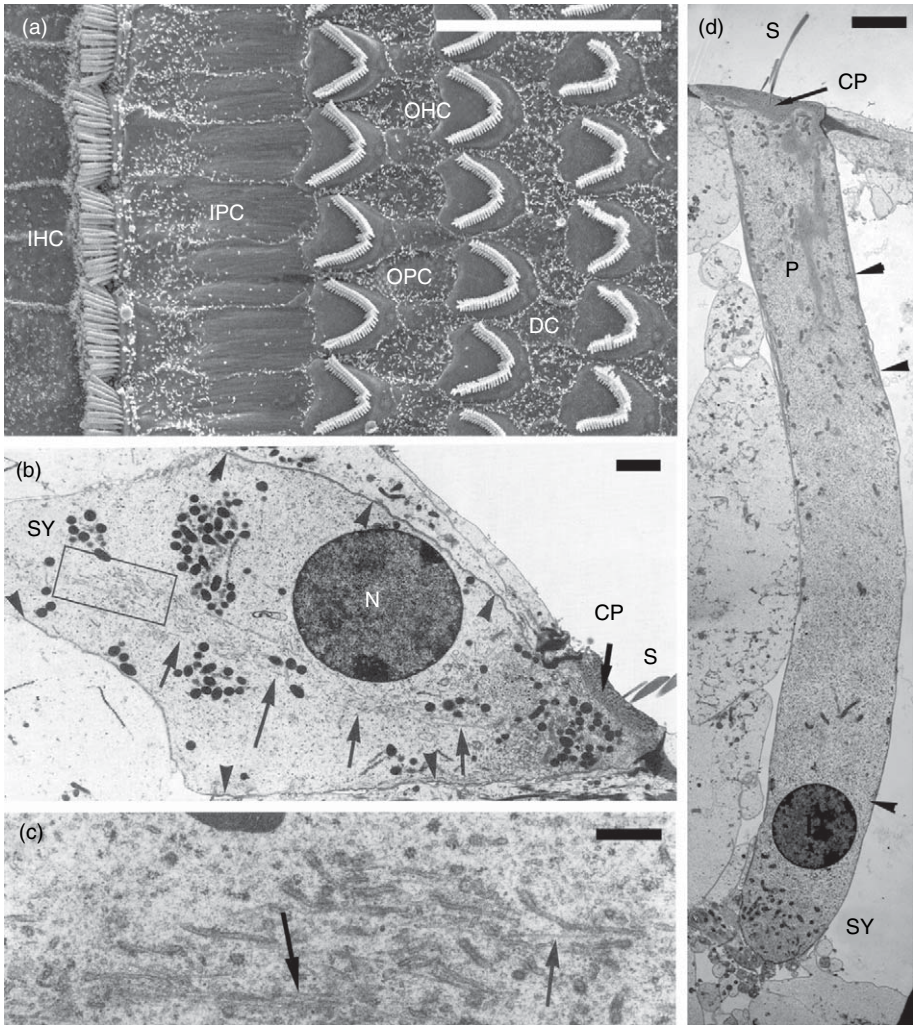

Figure 2 Organization of the sensory epithelium and the hair cells. (a) Scanning electron micrograph of the reticular lamina following removal of the tectorial membrane. The apices of the three rows of outer (OHC) and one row of inner (IHC) hair cells can be seen separated by supporting cells. The hair bundles of OHCs appear W-shaped, whilst those of IHCs appear more linear. Between the IHCs and the OHCs are the apices of inner pillar cells (IPC). The outer pillar cell (OPC) apices occur between OHCs of the first row, those of Deiters' cells (DC) between the remaining OHC rows. Scale bar = 20 μm. (b) Transmission electron micrograph of a guinea-pig IHC in longitudinal section showing stereocilia (S) projecting from the cuticular plate (CP). The cell body contains the nucleus (N) and a track of microtubules and vesicles (arrows) extending from the apex to the synaptic region (SY). The basolateral membrane has a subsurface cistern from the neck to just below the nucleus (arrowheads). The box is shown at higher enlargement in (c). Scale bar = 5 μm. (c) Membraneous tubules and vesicles are evident in association with longitudinally orientated microtubules (arrows). Scale bar = 500 nm. (d) Transmission electron micrograph of a guinea-pig OHC in longitudinal section. The apical stereocilia (S) and cuticular plate (CP), the lateral wall region, indicated by the arrowheads, and the synaptic region (SY) are illustrated. Note the central axial projection (P) of cuticular plate material. Scale bar = 5 μm. (b, c) Adapted from Furness, D. N., Hackney, C. M., and Steyger, P. S. 1990. Organization of microtubules in cochlear hair cells. J. Electron Microsc. Tech. 15, 261–279.

varies with species and position along the spiral, and there is a minimum of two rows of stereocilia always increasing in height stepwise across a bundle. The IHCs are supported by inner phalangeal cells and OHCs by Deiters' cells. Deiters' cells anchor the OHCs at their base in a cup and give rise to a strut which projects upward at an angle to terminate in the top of the organ of Corti (the reticular lamina) where it anchors adjacent OHC apices. Inner phalangeal cells almost completely enclose the IHCs. Between IHCs and OHCs are two rows of pillar cells which form a triangular arch in cross section, encompassing the longitudinally running tunnel of Corti (Figure 1).

The cochlear response to sound is related to the physical attributes of the array of hair cells and supporting cells, that is, the dimensions, angle, and shape of cells and projecting cellular processes, the basilar membrane, including changes in its width and thickness and the overlying tectorial membrane. These all vary systematically along the length of the spiral organ, and the result is a gradual change in mass and compliance that generates a cochleotopic gradient in resonant properties. Accordingly, sound input into cochlear fluids via the middle ear sets up traveling waves of displacement along the organ of Corti/basilar membrane complex such that low frequencies produce maximum displacement near the apex of the spiral and high frequencies near the base (see review by Robles, L. and Ruggero, M. A., 2001). The displacement is transferred to the hair bundles by means of the tectorial membrane, which contacts the OHC stereocilia and produces fluid movements that displace the IHC stereocilia. Movement of the hairs in the excitatory direction (i.e., toward the tallest row) depolarizes the hair cells whilst opposite deflections hyperpolarize them. The basilar membrane displacement also undergoes nonlinear amplification, via an electromechanical response attributed primarily to the OHCs, which enhances the separation of frequencies along the cochlea and the detection of low-intensity sound (see, e.g., review by Fettiplace, R. and Hackney, C. M., 2006a). In conjunction with physical changes, some aspects of the composition of the cells also vary systematically along the length of the spiral, with changes in the concentration of some proteins contributing to cochleotopic changes in the physiological properties of the organ of Corti.

Other auditory organs also contain hair cells and supporting cells of different types (see Chapter Phylogeny and Evolution of Ciliated Mechanoreceptor cells). The auditory epithelium of birds is a curved tapering ridge with two types of hair cell, short and tall. An overlying tectorial membrane similarly stimulates hair bundles. The cold-blooded vertebrates (amphibians and reptiles) also possess ridge-like auditory papillae with hair cells similar in overall organization to mammalian and avian hair cells (Figure 3) but of varying types often defined by differences in the geometric organization, size and morphology of the hair bundle (see, e.g., Manley, G. A., 1990; Hackney, C. M. *et al.*, 1993), and an overlying tectorial membrane, though not all hair bundles insert into it. In some amphibians, there are two auditory epithelia per inner ear whilst fish lack specific primary auditory epithelia but respond to auditory stimuli via other hair-cell epithelia in their inner ears (see, e.g., review by Popper, A. N., 2000).

3.06.1.2 Composition of the Cells of Auditory Epithelia

3.06.1.2.1 Hair cells

The hair cells are not only mechanically sensitive but also contribute to the general mechanical properties of auditory organs. These factors make their ultrastructure vital to the function of the hearing organs in a variety of ways; for example, in mammals, they must withstand and even contribute to the physical displacement of the basilar membrane in the organ of Corti whilst retaining a rapid, highly sensitive mechanotransduction mechanism. Thus, they are rich in cytoskeletal proteins, particularly actin, and the supporting cells are also structurally stiff because of large microtubule bundles and actin-rich anchoring structures. At the same time, the hair cells are innervated by nerve fibers of the cochlear nerve. IHCs are innervated by up to 20 afferent nerve fibers constituting around 90% of all afferent fibers, whilst several OHCs form synapses with branches from single nerve fibers that constitute the remaining 10% of afferents. The OHCs also receive direct input mainly from crossed olivocochlear efferents, whilst generally IHCs do not. Instead, the efferent innervation is received by their afferent fibers via *en passant* contacts from fibers of the lateral system, postsynaptic to the afferent terminal (see Chapter Genetic Hearing Loss).

The hair cells can accordingly be subdivided into an apical sensory pole containing the hair bundle which is the mechanotransduction apparatus that has evolved to detect mechanical stimuli and, at least in OHCs, is thought to contain a force-generating mechanism that may contribute to the cochlear amplifier (Chan, D. K. and Hudspeth, A. J., 2005;

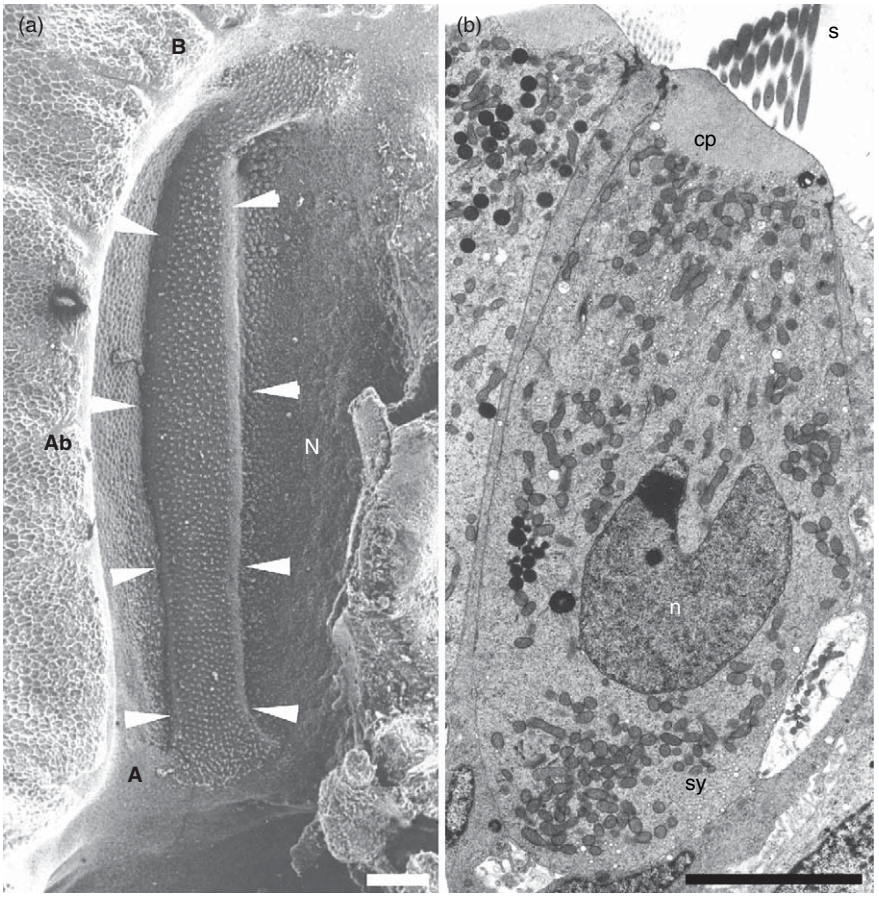

Figure 3 Auditory epithelium of a turtle. (a) Scanning electron micrograph showing the ridge-shaped epithelium (outlined by arrowheads), with the hair bundles appearing as light dots on the surface. High-frequency cells are located basally (**B**) and low-frequency cells apically (**A**). Auditory nerve fibers enter from the neural side (N) rather than the abneural (Ab) side. (b) Transmission electron micrograph of a hair cell from the turtle auditory epithelium. Like mammalian hair cells, these cells have an apical sensory region characterized by a stereociliary bundle (S) rooted into a cuticular plate (CP), and a basolateral region stretching down to the synaptic pole (SY). The nucleus (N) is central and here invaginated. The mitochondria are distributed throughout the cytoplasm but are more concentrated beneath the cuticular plate and nucleus, as is the case in mammalian cochlear hair cells.

Kennedy, H. J. *et al.*, 2005) and a basal synaptic pole which functions in both signaling to the central nervous system and receiving descending signals from the efferent auditory pathway (Figures 2 and 4). The extent of the synaptic region differs between cells; the OHCs can be relatively long cylinders, the length depending on species of origin and frequency location (Dannhof, B. J. *et al.*, 1991), with nuclei near their bases and synapses largely confined to a relatively small infranuclear region. The OHC lateral wall is a highly specialized region with a complex structure including layers of subsurface membraneous cisternae and a cytoskeletal cortical lattice. This region functions in the production of rapid cycle-by-cycle elongation/contractions involved in the biophysical amplification of basilar membrane motion (see, e.g., He, D. Z. *et al.*, 2003), which gives it properties distinct from either sensory or synaptic poles. In IHCs and other types of hair cells, this basolateral wall motility does not appear to be present.

The following descriptions will indicate the molecular organization of each of these regions in turn.

3.06.1.3 The Mechanotransduction Apparatus

The sensory pole of the hair cell is responsible for mechanotransduction (Corey, D. P. and Hudspeth, A. J., 1979a) and contains a complex apparatus that serves to deliver stimulus energy onto

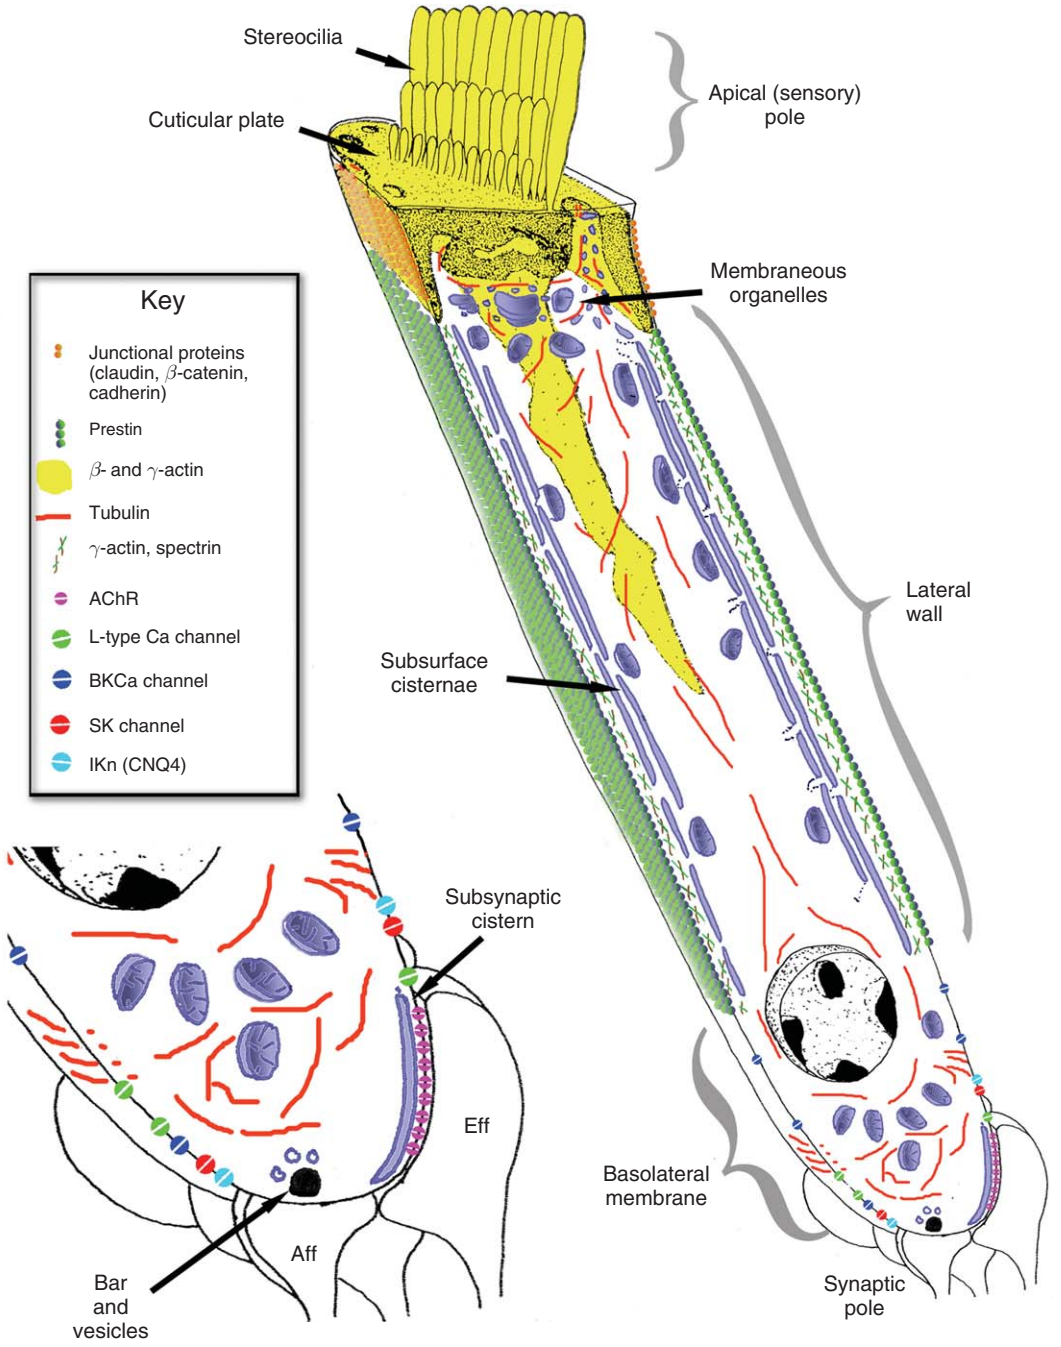

Figure 4 Diagram of an OHC showing the location of a number of important molecules as identified in the key. OHCs have a specialized lateral wall lined by cisternae and a cortical lattice. The plasma membrane contains a high density of prestin molecules. The stereocilia are rooted in the cuticular plate, both of which are rich in two nonmuscle isoforms of actin. (For clarity, other molecules important in the mechanotransduction apparatus have been omitted and are illustrated in a separate figure.) Around this region is the junctional complex composed of a number of molecules. The basolateral membrane and synaptic pole are illustrated at higher magnification on the lower left part of the plate. Note that the known ion channels associated with modulation of the receptor potential and neurotransmission are, for clarity, represented here although they are likely to be spread more apically among the prestin molecules. Membraneous organelles and cisternal membranes, including the subsynaptic cistern which apposes the efferent nerve endings, are depicted in blue. The synaptic bar and vesicles apposed to afferent nerve terminals are also shown, as is the microtubular cytoskeleton, composed of tubulin, depicted as red lines.

mechanoelectrical transduction (MET) channels in the hair-cell apex. This apparatus consists of the hair bundle (Figures 4 and 5) and an apical filamentous raft called the cuticular plate; the apical plasma membrane extends over the stereocilia and apical surface of the cuticular plate. Laterally there is a circumferential junctional complex around the plate that connects the cell with the apices of adjacent

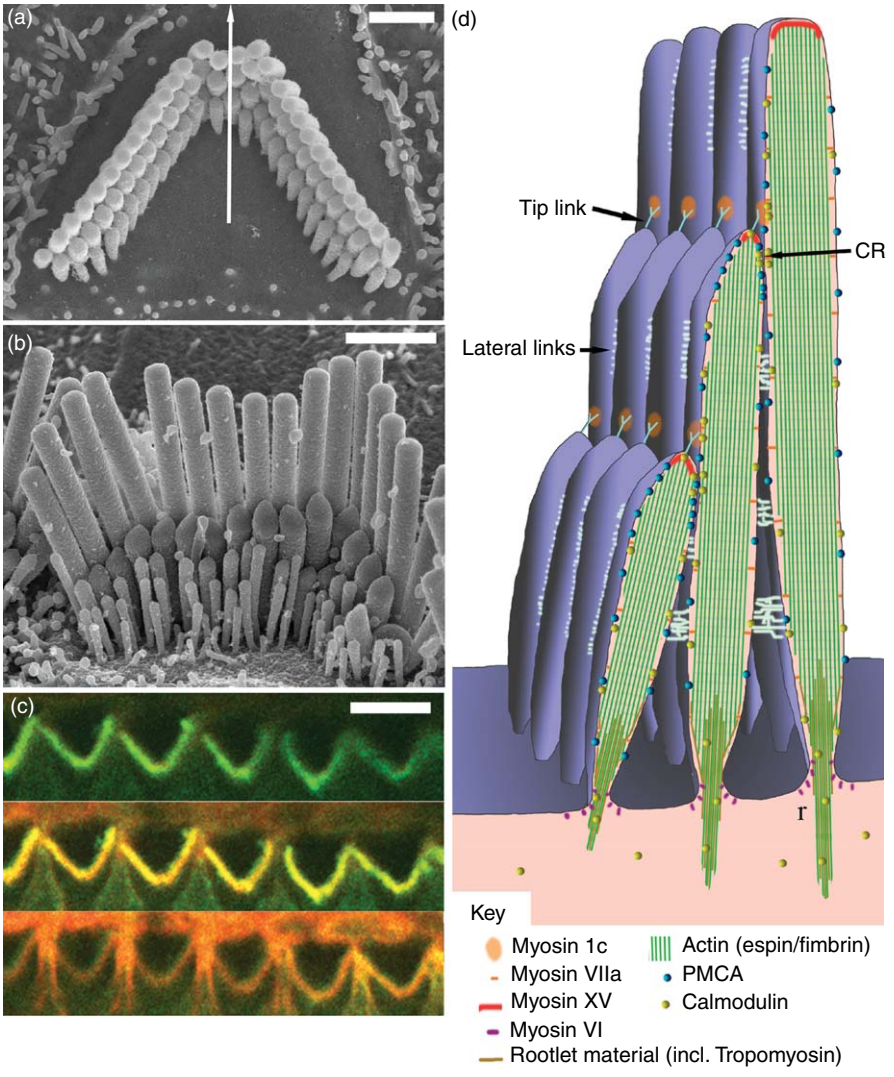

Figure 5 The stereociliary bundle and mechanotransducing apparatus. (a) Scanning electron micrograph of a rat OHC bundle. The direction of deflection of the bundle which leads to depolarization of the hair cell is shown. Scale bar = 1 μm. (b) Scanning electron micrograph of a rat IHC bundle. The bundle is more linear, and less precisely organized than the OHC, but shares most of the same anatomical features. Scale bar = 2 μm. (c) Confocal images of β (red) and γ (green) actin labeling in OHC bundles. The plane of section of the top image is near the stereociliary tips and moves lower through the middle and bottom panels. Colocalization, represented by a yellow color, is most apparent in the middle, whilst γ-actin labeling is stronger near the tips, and β-actin stronger near the ankles of the stereocilia. Scale bar = 10 μm. (d) Schematic diagram of a portion of a bundle showing the principle structures and molecules present, as indicated in the key. The stereocilia are linked by extracellular filaments, including the tip link which is forked. An actin paracrystal cross-linked by espin and fimbrin forms the core. Various myosin isoforms are enriched at different points as shown. Myosin XVa forms a cap over the actin core, myosin VIIa occurs along its periphery, myosin VI near the ankles, and myosin 1c, although found throughout the stereocilium, is enriched at the upper end of the tip link. Calcium ATPase (PMCA) and calmodulin are both associated with the plasma membrane but more concentrated in the tips of the stereocilia; calmodulin is known to be enriched at either ends of the tip link and in the contact region just below the tip link. At the lower end of the stereocilia, the shaft narrows to an ankle, and a small proportion of actin filaments appear to penetrate into the apex of the cell to form a rootlet (r) with dense material containing tropomyosin and calmodulin surrounding them. Putative localizations of the MET channels are depicted in Figure 6.

supporting cells, functionally separating the apical membrane from the basolateral membrane (Figure 4). This junctional complex contains β-catenin (Simonneau, L. *et al.*, 2003), cadherins (Mahendrasingam, S. *et al.*, 1997; Simonneau, L. *et al.*, 2003), and claudin 14 (Cldn 14 – Ben-Yosef, T. *et al.*, 2003). Null mutants for Cldn 14 have normal EPs but show rapid progressive loss of OHCs and slower IHC loss suggested to be due to altered ionic balances between endolymph and perilymph. Different isoforms of cadherin also show distinct distributions: N-cadherin is expressed in IHCs and E-cadherin in OHCs (Simonneau, L. *et al.*, 2003). Also around the pericuticular regions of IHCs, there is immunocytochemical evidence for the presence of a plasma membrane calcium ATPase isoform, PMCA3 (Dumont, R. A. *et al.*, 2001) presumably also assisting in ion control in that vicinity.

The hair bundle detects mechanical stimuli, directing the energy of the stimulus to the MET channels located in the stereocilia. The anatomical organization of the mechanotransduction apparatus of all hair cells, therefore, is quite precise; the stereocilia form well-defined rows, each row increasing in height stepwise in one direction across the bundle (Figure 5). Developmentally, there is a single kinocilium originating from an apical basal body, located initially in the center of the bundle at least in mammalian vestibular hair cells, which migrates to end up in the middle behind the tallest row (Forge, A. *et al.*, 1997). In the mature hair bundle, a line drawn from the kinocilium or basal body position to the middle of the shortest row of stereocilia represents an axis of symmetry whereby the structure on one side is an approximate mirror image of the other side and also lies along the excitatory–inhibitory axis of the bundle (Figure 5). The kinocilium is composed of a microtubular axoneme and is retained throughout life in all hair cells except for mammalian auditory hair cells where only the basal body remains in adults.

The stereocilia, and kinocilium when present, are covered by a surface coat of carbohydrate (Santi, P. A. and Anderson, C. B., 1987) and are linked together by a distinct array of extracellular strands called cross-links (Bagger-Sjoback, D. and Wersall, J., 1973; Pickles, J. O. *et al.*, 1984; Furness, D. N. and Hackney, C.M., 1985; Hackney, C. M. *et al.*, 1993). Typically, each shorter stereocilium is linked to a taller one in the adjacent row by an extracellular link emanating obliquely from the tip. The two attached stereocilia and the link ordinarily lie along a line that runs more or less parallel to the axis of symmetry of the bundle (Pickles, J. O. *et al.*, 1984; Furness, D. N. and Hackney, C. M., 1985). The tip link bifurcates part-way along its length, in examples from most vertebrate classes (see review by Furness, D. N. and Hackney, C. M., 2006), and at its upper end, the two strands attach to two points on the side of the taller stereocilium, coinciding with a circular plaque of electron dense material that is consistently present in all vertebrate classes (Figures 5 and 6). At its lower end, the tip link inserts into the shorter stereocilium near a dense cap of material over the actin core. Ultrastructural studies suggest that intracellular connections link the lower end of the tip link to this cap (Osborne, M. P. *et al.*, 1988; Kachar, B. *et al.*, 2000). Other cross-links include lateral links holding stereocilia together in all directions (Figure 6) and connectors below the tips, also joining short stereocilia to taller ones, in some cases in a region where the adjacent membranes are closely apposed, called the contact region (Hackney, C. M. *et al.*, 1992). Thus, in different hair-cell types, there are different constellations of links which can be distinguished to some extent by anatomical, immunological, and enzymatic means (see, e.g., Pickles, J. O. *et al.*, 1984; Furness, D. N. and Hackney, C. M., 1985; Osborne, M. P. and Comis, S. D., 1990; Goodyear, R. and Richardson, G. P. 1999; 2003), but all hair cells seem to possess tip links.

As noted above, during sound stimulation of the mammalian cochlea, displacement of the hair bundles occurs which, because of the sinusoidal nature of the traveling wave, will deflect the bundle cyclically along its axis of symmetry, alternately displacing the stereocilia in a direction toward and away from the tallest row. The likely outcome of displacement toward the tallest row of stereocilia is tension being placed on the tip links which could deliver energy and gate the MET channels at one or both ends of the link, resulting in a flow of potassium and calcium ions into the cell from the endolymph. Opposite displacement closes the channels restricting the current flow. Physiological evidence certainly accords with this hypothesis, since deflections toward the tallest stereocilia depolarize the cell and opposite displacements hyperpolarize it. When the MET channel opens, calcium entry initiates calcium-sensitive processes which include both rapid and slower force production that changes the operating point of the mechanotransduction apparatus (adaptation – see review by Fettiplace, R. and Hackney, C. M., 2006a).

Attempts are still being made to identify the different molecular composition of these components of

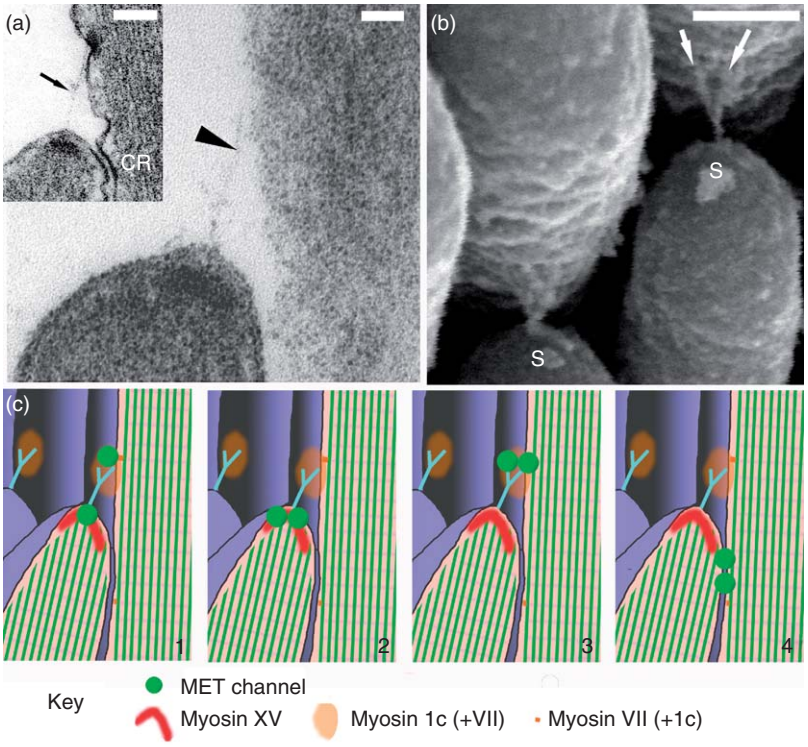

Figure 6 Possible models of the mechanotransduction apparatus. (a) (inset and main panel) Transmission electron micrographs of structures associated with gating of the MET channels. The tip link (arrow) runs between the tip of a shorter stereocilium and an adjacent taller stereocilium and appears to be forked between the two (arrowhead). The contact region (CR) is located just below the tip of the shorter stereocilium and is a point of close apposition with the taller stereocilium. Scale bars = 100 nm (inset) and 50 nm (main picture). (b) Scanning electron micrograph showing that each shorter stereocilium tip (S) is contacted by a tip link. The two forks are also illustrated (e.g., arrows). Scale bar = 100 nm. (c) Panels 1–4: different possible locations for the MET channels (green spheres). There is evidence for each of these models, but no one model currently satisfies all of the experimental data.

the mechanotransduction apparatus, in particular the identity of the MET channel itself and the composition of the tip links and associated adaptation mechanisms. The predominant apical material, the cytoskeletal protein actin, forms filaments with high-tensile strength that contribute to stiffness and motility in a variety of other cells throughout the body, including muscle cells. Between 30 and 3000 (depending on species, location, and hair-cell type), actin filaments fill the stereocilium, forming a paracrystalline bundle that constitutes the core (see review by Furness, D. N. and Hackney, C. M., 2006). The cuticular plate is composed of a network of actin filaments arranged in at least two domains in chick hair cells: a peripheral ring inside the junctional complex and a central matrix. Thus, the hair cell apices contain at least three different assemblies of actin, and these have their own constellation of associated proteins which help define and potentially modify their properties (Drenckhahn, D. *et al.*, 1991).

Actin is likely to determine the gross mechanical properties of the bundle and its anchor points. General actin stains, such as phalloidin or antibodies that are not isoform specific, label stereocilia and cuticular plate in all hair cells. However, where it has been examined (in chick and guinea pig), two specific isoforms of actin are present, cytoplasmic β- and γ-actins (Figure 5), which are distinct from the common muscle isoforms (Slepecky, N. B. and Savage, J. E., 1994; Hofer, D. *et al.*, 1997; Furness, D. N. *et al.*, 2005). Within the hair cells, these isoforms have varying ratios in different regions. Thus, the stereocilia and cuticular plate in mammals contain both, but there appears to be a peripheral enrichment of β-actin in the lower stereociliary shaft, with γ-actin more prominent toward the tip (Furness, D. N. *et al.*, 2005). In chick hair cells, β-actin may not be present in the cuticular plate (Hofer, D. *et al.*, 1997). It is not known how these isoform distributions are specified during development, nor has the relative

distribution been determined in hair cells from other vertebrates. The functional significance of the different isoform distributions is still being investigated.

The actin filaments in mammalian auditory stereocilia are cross-linked by espin which appears to be necessary for proper stereociliary elongation during development (Zheng, J. *et al.*, 2000) and, in adults, also by I-plastin (fimbrin – Pack, A. K. and Slepecky, N. B., 1995). During development, T-plastin is transiently expressed in the stereocilia (Daudet, N. and Lebart, M. C., 2002).

The stereocilia are thus stiffened by this core of actin and cross-linking proteins. Low levels of immunocytochemical labeling for the elastic molecule, spectrin, have also been detected along the shaft of the stereocilium, but this protein is more prominent in the cuticular plate and lateral wall (Mahendrasingam, S. *et al.*, 1998). The stereocilia also contain myosins (Figure 5), which commonly interact with actin to produce motility; myosin VIIa is located along the length of the actin core at its periphery (Hasson, T. *et al.*, 1997). Here, it may be associated with vezatin which can form links between catenin–cadherin complexes and myosin VIIa (Kussel-Andermann, P. *et al.*, 2000). Defects in the genes encoding myosin VIIa result in disturbance of hair bundle organization; the stereocilia can become splayed and, in scanning electron micrographs, some appear to have fallen onto the reticular lamina. These bundles require greater displacement to stimulate the hair cell than normal (Kros, C. J. *et al.*, 2002). Thus, myosin VIIa may be involved in maintaining the integrity of the bundle. Other proteins that may interact with myosin VIIa are harmonin, SANS, cadherin 23, and protocadherin 15, as defects in the genes for all of these proteins are associated with Ushers syndrome (Frolenkov, G. I. *et al.*, 2004 for a review) and PHR1, an integral membrane protein found in hair cells (Xu, S. *et al.*, 2004; Etournay, R. *et al.*, 2005).

A second myosin, myosin 1c, is distributed similarly to myosin VIIa but may be more concentrated near the stereociliary tips of shorter stereocilia and the upper end of the tip link in bullfrog where it is thought to be a component of the upper dense plaque (Garcia, J. A. *et al.*, 1998; Steyger, P. S. *et al.*, 1998). Genes for orthologs of myosin 1c have been identified in mouse (Crozet, F. *et al.*, 1997), and a transgenic model in which myosin 1c was manipulated suggest that it is involved in slow adaptation (Holt, J. R. *et al.*, 2002). Myosin 1c also interacts with PHR1 and calmodulin; all of these proteins may therefore be implicated in adaptation (Etournay, R. *et al.*, 2005).

Myosin XVa has been found to cap the actin core of mammalian stereocilia from the start of bundle development and in adulthood (Belyantseva, I. A. *et al.*, 2003; Rzadzinska, A. K. *et al.*, 2004) and is responsible for developmental delivery of whirlin to the tips of stereocilia, a process which is defective in whirler mice (Mburu, P. *et al.*, 2003). When either of the genes for myosin XVa and whirlin is defective, short stereocilia and deafness are the result; hence, both proteins are required for normal stereociliary growth (Belyantseva, I. A. *et al.*, 2005). Whirlin also associates with erythrocyte protein p55 and protein 4.1R, and it has been proposed that these form a complex involved in stereociliary development (Mburu, P. *et al.*, 2006). The expression of whirlin, p55 and protein 4.1R reduces at the end of development. During development, whirlin is also transiently present near the ankle regions, suggestive of an association with myosin VIIa as noted above.

Myosin VI has been localized to the hair-cell apex and cytoplasm, and in particular in developing hair bundles (Hasson, T. *et al.*, 1997). In zebrafish, it is localized to the ankle regions of stereocilia. A myo6 defective zebrafish mutant shows loss of mechanotransduction, and it is suggested that myosin VI is involved in tautening, then anchoring, the stereociliary membrane (Kappler, J. A. *et al.*, 2004). In mouse, defects in the *Myo,6* gene result in the Snell's Waltzer phenotype which has disorganized hair bundles (Avraham, K. B. *et al.*, 1997). Thus, myosin VI may also be involved in hair bundle development and maintenance.

The tip link is an extracellular filament and from immunocytochemical data and studies of mutant zebrafish, reported to be composed of cadherin 23 (Siemens, J. *et al.*, 2004; Sollner, C. *et al.*, 2004). However, in some studies, cadherin 23 has been detected developmentally but not in adults (Boeda, B. *et al.*, 2002). One reason for this discrepancy may be that there are multiple tip links in immature hair cells, and thus, cadherin may show a higher, more detectable, signal developmentally (see, Furness, D. N. *et al.*, 1989). Other studies suggest that protocadherin 15, which may be involved in the lateral links (see below), could be associated with the tip link (Ahmed, Z. M. *et al.*, 2006). Thus, it appears likely that some form of cadherin may be contained within the tip-link complex. If protocadherin 15 is part of the tip link, its interaction with myosin VIIa (Senften, M. *et al.*, 2006)

could form the basis of an adaptation motor in the MET apparatus.

Freeze-fracture studies show that the tip link is a braided macromolecule with an organization that suggests inelasticity (Kachar, B. *et al.*, 2000). This has led to the suggestion that the tip link is not itself the gating spring but connected to it, perhaps via ankyrin at the membrane that is then connected to the MET channel. Modeling has suggested that ankyrin has appropriate properties for a gating spring that could open the channel and is a component of transient receptor potential (TRP) channels, one candidate for the MET channel (Sotomayor, M. *et al.*, 2005).

Whilst the tip link seems to be anatomically, chemically, and structurally distinct from the lateral links, the latter also similarly seems to contain protocadherin 15 and myosin VIIa and possibly cadherin 23, especially those connecting to the kinocilium in hair cells that possess the latter. There are subsets of these links, which are differentially susceptible to agents such as BAPTA (Goodyear, R. and Richardson, G. P., 1999). Associated with all the links are keratan sulphate proteoglycans (Katori, Y. *et al.*, 1996).

The identity and location of the MET channels themselves remains controversial (see Figure 6 and Chapter Auditory Scene Analysis). Clues to the channel's identity may come from knowledge of its physiological properties. It has a large unitary conductance of between 50 and 160 pS (from chick, mouse, and turtle data *in vitro*). The conductance increases to as much as 300 pS when single channel measurements are made in the presence of low (50 μM) calcium which is a permeant blocker. The pore size is of the order of 1.26 nm (Farris, H. E. *et al.*, 2004). The channel can be blocked by other cations, such as magnesium, in millimolar concentrations, gadolinium (K_I 10 μM), and lanthanum (K_I 3.8 μM), by the diuretic amiloride (K_I 50 μM) and its derivative benzamil (K_I 6 μM), by aminoglycoside antibiotics such as dihydrostreptomycin (K_I 8–44 μM, varying with calcium concentration), and by several other agents (see review by Fettiplace, R. and Ricci, A. J., 2006b). None of the blockers yet found are irreversible, and so they are not effective as a means of isolating the channel protein biochemically. Estimates of the number of functional channels per stereocilium indicate that there may be one or (more likely) two, although this does not preclude the possibility that there could be nonfunctional channels or subunits *en route* through the hair cell or stereocilia (Hackney, C. M. *et al.*, 1992). Thus, the few channels per hair cell (about 100 or so in IHCs) coupled with the small number of hair cells in a cochlea or vestibular organ mean that the possibility of isolating channel proteins for characterization is limited.

There are a number of mechanosensory channels to consider as candidates for MET channels, in both prokaryotes and eukaryotes, and in the latter, in invertebrates and vertebrates, with a wide range of properties. These include the vertebrate MDEG – epithelial sodium channel superfamily. Like the hair-cell MET channels, these are blocked by amiloride but at lower concentrations, and they have a unitary conductance that is smaller than that of the MET channel. Another possible channel type is the cyclic nucleotide-gated channel. These are similar to the MET channel with respect to their amiloride sensitivity and calcium block but also have low unitary conductance (Farris, H. E. *et al.*, 2004). As a result of studies on invertebrate mutants with mechanosensory deficits, attention has also been drawn to the TRP channels. Studies of *Drosophila* revealed that NOMPC, a relative of the TRP channel OSM-9, was involved in mechanosensory bristles (Walker, R. G. *et al.*, 2000), and recent studies of zebrafish using antisense oligonucleotides to knock down channel function produced initial deafness and balance dysfunction (Sidi, S. *et al.*, 2003). NOMPC does not occur in mammalian hair cells, although another TRP channel TRPA1 has been suggested to be present. Antibodies to this channel label the stereocilia, and short interfering RNA for TRPA1 introduced into hair cells *in vitro* prevent mechanotransduction (Corey, D. P. *et al.*, 2004). However, knockout mice lacking TRPA1 appear to retain normal auditory function (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006), an observation that argues against this channel being the MET channel.

Another possible channel in the hair-cell apical membrane could be associated with purinergic receptors. There is evidence of ATP-gated channels in the stereocilia of hair cells, and labeling has been obtained in mammalian cochlear hair bundles for $P2X_2$ receptors. The precise location and function of these channels/receptors remain to be determined, but it has been suggested that they represent a possible way to modulate the transcellular driving force for mechanoelectrical and electromechanical transductions (Housley, G. D. *et al.*, 1999).

Recent immunocytochemical studies have also suggested the presence of two further types of channel in the hair-cell apex. The first is a chloride

channel, CLIC5, known to be associated with actin that has been detected in the region where radixin is found. A mouse mutant, jitterbug which lacks the CLIC5, has abnormal hair bundles and shows reduced labeling for radixin, suggesting that an interaction between the two is necessary for normal stereociliary formation (Gagnon, L. H. *et al.*, 2006). The second is an acid-sensing channel, ASIC1b (Ugawa, S. *et al.*, 2006). The ASICs are proton-gated sodium channels, also of the mammalian degenerin (MDEG) family, and have been localized especially near to the ankle region.

Despite all of these studies, the identity of the MET channel remains to be determined beyond doubt. It is possible that it is a channel common to other epithelia or neurones rather than one specific to the acousticolateralis system and is thus hard to distinguish from the other channels in this system.

The calcium sensitivity of mechanotransduction and its effects on adaptation mean that the MET apparatus also needs calcium-regulating and calcium-sensing proteins. In guinea-pig cochlear hair cells, calmodulin is enriched at the tips of the stereocilia, at either end of the tip link, and in the stereociliary contact region (Furness, D. N. *et al.*, 2002b; Figures 5 and 6). In these locations, calmodulin could be an integral component of the MET channel itself, since calcium appears to have a direct influence on channel gating. However, myosin molecules are likely to bind calmodulin, so some of the calmodulin in these regions may reflect an interaction with myosin 1c, myosin VIIa, representing the slow adaptation motor, or myosin XVa. In mammals, calmodulin also occurs along the lateral wall of the stereocilia where the myosin VIIa is found and so could also influence motile properties of the bundle from this location, more indirectly affecting the gating of the channels.

In the vicinity of the mechanotransduction apparatus, there is also thought to be a high density of plasma membrane calcium ATPases (pumps – PMCAs) that work together with endogenous diffusible calcium buffers, such as calbindin and parvalbumin, to exercise fine control over calcium concentration and thus regulate its effects on the MET channel (Figures 5 and 6). PMCAs have been immunolocalized in both adult frog sacculus and mammalian cochlear hair bundles, and a mouse mutant lacking PMCA (the deaf-waddler mouse) and PMCA2 knockouts become deaf and display vestibular dysfunction (Kozel, P. J. *et al.*, 1998; Street, V. A. *et al.*, 1998). The different isoforms of PMCA show distinct distributions; thus, the stereocilia contain predominantly or exclusively PMCA2 (Dumont, R. A. *et al.*, 2001), and there is evidence of rapid turnover of this protein in the stereociliary membrane (Grati, M. *et al.*, 2006).

Other proteins could also contribute to the control of calcium. A number of calcium buffers have been detected in hair cells. These include, parvalbumin-3 (Heller, S. *et al.*, 2002), a form of parvalbumin-β (oncomodulin), calbindin-D28K, and calretinin (Hackney, C. M. *et al.*, 2003; 2005), some of which may be involved in control of local calcium concentrations in the bundle associated with the modulation of mechanotransduction.

In the mouse, calretinin is present in hair cells developmentally but disappears, at least in OHCs, by P22 (Dechesne, C. J. *et al.*, 1994). The other calcium buffers are likely to play various roles in hair cells, and they are found in adults in the cytoplasm of the cell body (discussed further below). In rat cochlear hair cells, the concentration of these buffers appears to be lower in the stereocilia than in the hair-cell body (Hackney, C. M. *et al.*, 2005), a situation which differs from that seen in turtle cochlear hair cells where buffer concentrations appear to be similar in both compartments (Hackney, C. M. *et al.*, 2003). This implies an evolutionary change in calcium-handling mechanisms in the stereocilia perhaps related to changes in the sensitivity and frequency selectivity of the mammalian cochlea.

At their insertion into the apex of the hair cell, the stereocilia become narrower. In this vicinity and extending both up into the shaft and down into the cuticular plate is a rootlet of dense material which accompanies a smaller number of actin filaments that appear to continue into the plate. In mammals, this remains as a tightly packed bundle in the cuticular plate, surrounded by a clear zone relatively devoid of filaments (Itoh, M., 1982). In other vertebrates, the filaments may fan out in a conical array (Tilney, L. G. *et al.*, 1980; Hackney, C. M. *et al.*, 1993). The composition of the dense material in the mammalian rootlet remains obscure, although tropomyosin and calmodulin have been localized there in adult guinea pigs (Slepecky, N. and Chamberlain, S. C., 1985), and as noted before, myosin VI is present in the ankle region (Kappler, J. A. *et al.*, 2004).

Tropomyosin has a regulatory function modulating acto-myosin interactions in muscle. It is thus possible that the rootlet represents the site of an active mechanism that influences stereociliary stiffness or motion and perhaps is associated with force production. However, the relatively long distance

from the MET channels and the comparatively low speed of an enzymatically acting force-producing motor may limit how rapidly such a mechanism can work to modulate mechanotransduction at acoustic frequencies, which would be necessary for a process in this location to contribute significantly to the cochlear amplifier. On the other hand, a slower modulatory force might be used to tune the hair cells and optimize bundle properties better to the frequency location of the cells.

The ankle membrane of the stereocilia contains radixin (Pataky, F. *et al.*, 2004). Radixin interacts with myosin VIIa and myosin XVa, indicating possible formation of complexes between these proteins, binding actin to the membrane.

Other cytoskeletal and related proteins that have been detected in the cuticular plate include spectrin (Pack, A. K. and Slepecky, N. B., 1995; Mahendrasingam, S. *et al.*, 1998) profilin, I-plastin (fimbrin), α-actinin (Slepecky, N. B. and Ulfendahl, M., 1993), and calmodulin (Furness, D. N. *et al.*, 2005) as well as the aforementioned isoforms, myosin VI and myosin VIIa. The organization of the plate, at least by electron microscopy, is difficult to elucidate, but there are clearly arrays of cytoskeletal molecules within it or associated with it, examples being the striated Friedmann's body (Slepecky, N. B. *et al.*, 1981) and the infracuticular extension or network (Carlisle, L. *et al.*, 1988), the latter possibly unique to guinea pigs. This infracuticular protrusion is largest in apical long OHCs in guinea pig and decreases in size toward the base of the cochlea and from the third to the first row of OHCs. The cuticular plate of mammals also contains layers of discrete dense bodies, which may be enriched in α-actinin (Slepecky, N. and Chamberlain, S. C., 1985). In IHCs, the layers closer to the apical membrane contain larger-sized densities than those situated closer to nucleus; in addition, the cuticular plate may also be thicker in high-frequency regions (Furness, D. N. *et al.*, 1990). Thus, there are organizational features that suggest that the cuticular plate may influence hair bundle mechanics, but these properties require further biophysical investigation.

The apical membrane has some other structural and molecular features which indicate that active membrane cycling mechanisms may be occurring. The cuticular plate is interrupted by a wide channel of cytoplasm that reaches up to the apical membrane (Figures 4 and 7). In the membrane over this channel, there are frequently coated pits (Furness, D. N. *et al.*, 1990) and an apical subsurface cistern is also present in both IHCs and OHCs (Lim, D. J., 1986; Furness, D. N. *et al.*, 1990) of the mammalian cochlea. Endocytotic pits have been described in turtle cochlea (Hackney, C. M. *et al.*, 1993) and bullfrog sacculus (Kachar, B. *et al.*, 1997) at this location. Active membrane uptake has been confirmed in this region in both IHCs and OHCs by using the dye FM-1-43 (Gale, J. E. *et al.*, 2001; Meyer, J. *et al.*, 2001; Griesinger, C. B., *et al.*, 2002; 2004). In the IHCs, it has been estimated that approximately 0.5% of the surface area of the cell can be endocytosed each second. The membrane taken up seems to be transported to the base of IHCs by kinesin-dependent trafficking (Griesinger, C. B. *et al.*, 2002), probably along tracks of microtubules (Figures 2 and 7) that have been described running through the cell (Steyger, P. S. *et al.*, 1989; Furness, D. N. *et al.*, 1990; Kachar, B. *et al.*, 1997) where it appears to be accumulated near the synaptic pole perhaps associated with replenishment of synaptic membrane (Griesinger, C. B. *et al.*, 2002). Such a mechanism could also be indicative of an apical membrane recycling process, perhaps allowing turnover of the MET channels, although the source of new apical membrane has not been determined.

3.06.1.4 The Basolateral Membrane

The basolateral membrane region of hair cells, like other epithelial cells, is compositionally distinct from the apical membrane partly because of the periapical tight junctions, which are likely to restrict interchange of membrane components, and partly because of differences in cytoskeletal structures beneath the membranes. Whilst in the apical membrane, the ion channels presently thought to occur are the MET channels, ATP-gated channels, CLIC5 and ASIC1b, the basolateral membrane has a different complement of channels involved in shaping the receptor potential, calcium control and in neurotransmitter release (Figure 7).

The afferent synapses onto all hair cells are often called ribbon synapses as a consequence of their electron dense presynaptic bars or bodies, the shape of which varies between different hair-cell types. In mammalian IHCs, the synaptic bodies are usually tear-drop shaped, whereas in many nonmammalian vertebrates, they are round (Figure 7). They are surrounded by a halo of vesicles which are presumed to contain neurotransmitter. Other vesicles occur in the cytoplasm around these sites. The synaptic bar contains the marker ribeye in bullfrog saccular hair

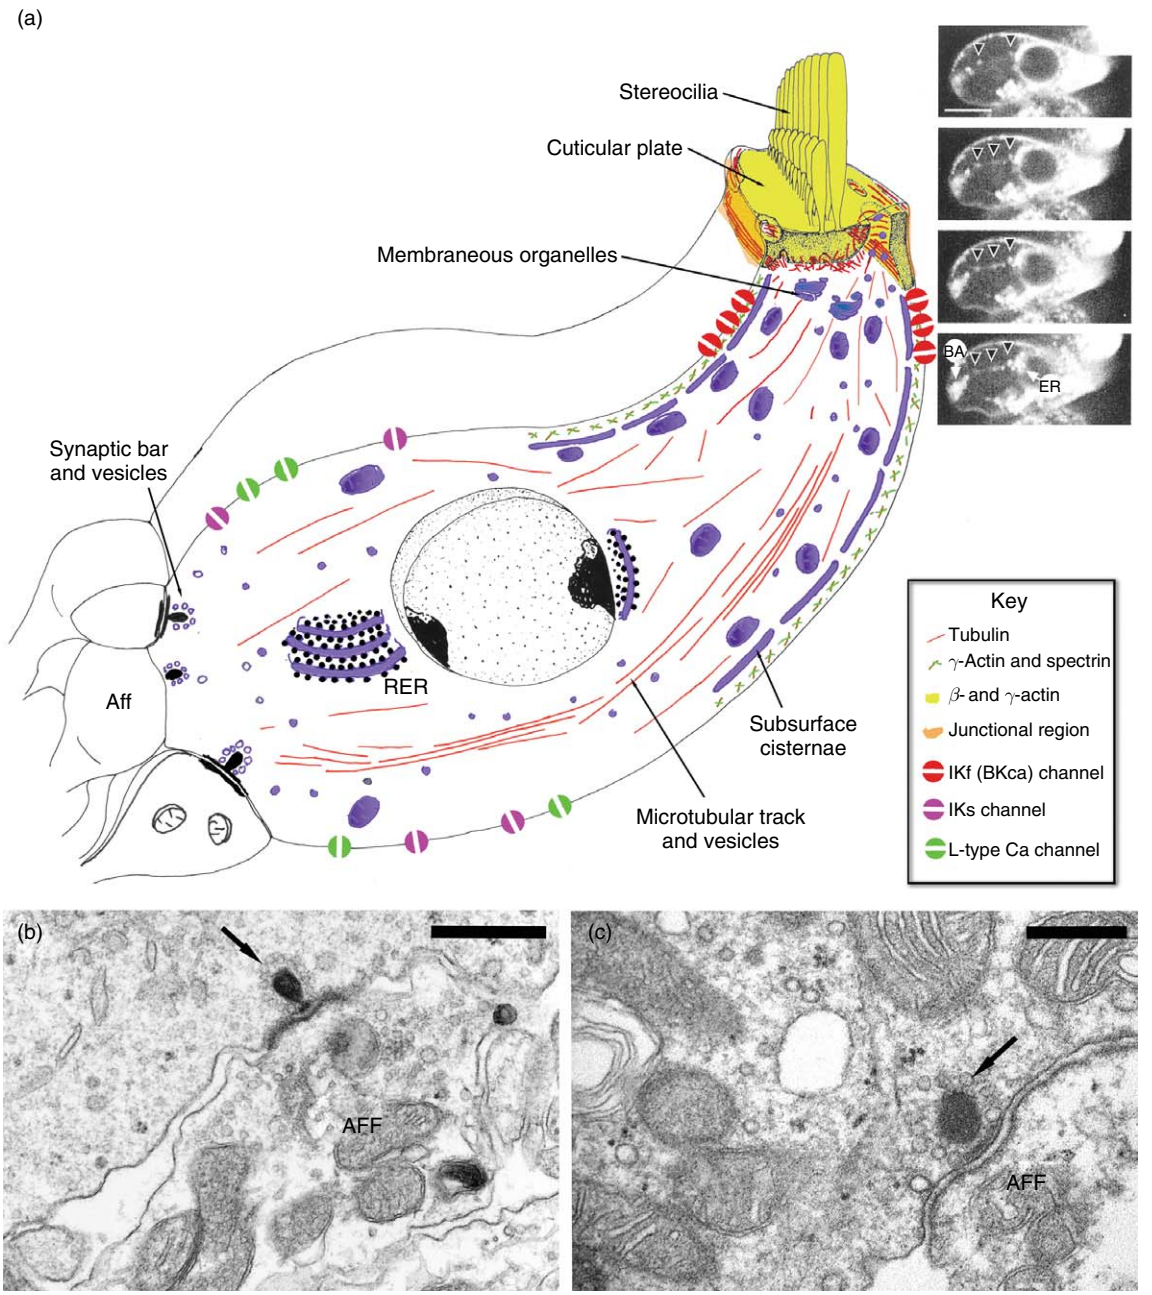

Figure 7 (a) Schematic diagram of an IHC showing several important molecules (see key for details). The IHC plasma membrane is lined by cisternae and a cortical lattice but lacks prestin. Ion channels of the basolateral membrane and synaptic region are mostly represented near the synapse, although in mammals BKCa channels may be mainly located in the neck region as indicated. Membraneous organelles, cisternal membranes, and vesicles are depicted in blue. The synaptic bars (ribbons) apposed to afferent nerve terminals are also shown. The extensive microtubular cytoskeleton, depicted as red lines, includes a specific track running through the cell (as illustrated microscopically in Figure 2). The inset shows time-lapse confocal images of a live IHC labeled with the dye FM 1-43, illustrating apico-basal movement of membrane along a track probably corresponding to the longitudinally running microtubules. Scale bar = 10 μm. (b) Structure of the IHC synapse viewed by transmission electron microscopy. Note the teardrop-shaped dense bar surrounded by a halo of vesicles (arrow) adjacent to pre- and postsynaptic densities at the synapse with afferent (AFF) nerve terminals. Scale bar = 500 nm. (c) Transmission electron micrograph showing the similar dense bar and vesicles (arrow) associated with AFF terminals onto a turtle hair cell. Scale bar = 500 nm. (Inset in a) reproduced from Griesinger, C. B., Richards, C. D., and Ashmore, J. F. 2002. FM1-43 reveals membrane recycling in adult inner hair cells of the mammalian cochlea. J. Neurosci. 22, 3939–3952, with permission, Copyright 2002 by the Society for Neuroscience.

cells (Zenisek, D. *et al.*, 2003) that is probably anchored to the membrane by the presynaptic scaffolding protein, Bassoon (Nemzou, N. R. M. *et al.*, 2006), since the anchoring of the bars is impaired in Bassoon-deficient mice (Khimich, D. *et al.*, 2005). Nemzou N. R. M. *et al.* (2006) found that the synaptic region of hair cells also contains Piccolo, which is part of the structural organization of the presynaptic specialization in neurones (see review by Schoch, S. and Gundelfinger, E. D., 2006), and cysteine string protein which is a component of synaptic (Mastrogiacomo, A. *et al.*, 1994) and other export vesicles, both noted for their functioning in exocytosis of neurotransmitter vesicles. Another molecule called otoferlin has been suggested from genetic and molecular studies to be part of the presynaptic complex (Roux, I. *et al.*, 2006) although it has also been implicated in vesicle trafficking from other regions of the hair cell (Schug, N. *et al.*, 2006). Although the molecular details are still being investigated, the synaptic bar is presumed to function in rapid release of the synaptic vesicles (see, e.g., Schnee, M. E. *et al.*, 2005) which is impaired when the bar is not anchored properly (Khimich, D. *et al.*, 2005). In OHCs, the synaptic structure is less clear-cut. The OHCs receive afferent innervation, but the synaptic bars and vesicles are less well defined (Furness, D. N. *et al.*, 2002a).

At their afferent presynaptic specializations the IHCs are contacted by the radial neurites of the type I spiral ganglion neurones. Whilst it is not our intention to discuss in detail the molecular composition of the neurones or the role of afferent neurotransmission, it is noteworthy that the postsynaptic membrane possesses glutamate receptors, in particular GluR2/3 and GluR4 (for review, see Parks, T. N., 2000). GluR4 may also be localized presynaptically in the IHC membrane (Furness, D. N. and Lawton, D. M., 2003). The hair cells may also express metabotropic glutamate receptors (Oestreicher, E. *et al.*, 2002), phosphate-activated glutaminase (Takumi, Y. *et al.*, 1999), and the vesicular glutamate transporter, VGLUT1 (Furness, D. N. and Lawton, D. M., 2003). These various proteins are associated with the handling of glutamate, the likely neurotransmitter, by the hair cells and their afferent endings.

The plasma membrane channels present in mammalian auditory hair cells give rise to a number of membrane currents detectable using intracellular recording techniques which are implicated in control of the membrane potential and transmitter release. The identification of these channels is primarily based on their physiological characteristics, but in some cases, molecular biological, genetic, and immunocytochemical data have also contributed. The three main categories are sodium, potassium, and calcium channels.

Sodium currents have been detected in hair cells, indicating the presence of sodium channels. These are tetrodotoxin-sensitive channels normally associated with spiking activity. These have been detected in the immature mammalian cochlea where IHCs transiently produce spontaneous calcium-based action potentials (Beutner, D. and Moser, T., 2001; Marcotti, W. *et al.*, 2003) prior to the onset of hearing. The role of this spiking may be to provide a signal for the maturation of synaptic function, and it is accompanied by membrane capacitance changes indicative of exocytosis. The exocytotic mechanism is likely to release glutamate from the hair cells, prior to the acquisition of functional auditory responses, which could help to drive the connection of afferent nerve synapses with the IHCs.

Most of the studies of potassium currents have been carried out on nonmammalian vertebrates, where their contribution to electrical tuning and other mechanisms associated with variations in the response to frequency has been well established (see, e.g., Art, J. J. and Fettiplace, R., 2006). However, similar potassium currents have also been found in mammalian hair cells. One of these is an inwardly rectifying current (K_{IR}) identified first in bullfrog vestibular hair cells (Corey, D. P. and Hudspeth, A. J. 1979b) but subsequently found in the cochlea of chick (Ohmori, H., 1984), turtle (Art, J. J. and Fettiplace, R., 1987), and mouse (Marcotti, W. *et al.*, 1999). In chick and turtle, these currents are inversely correlated with frequency.

Outward potassium currents have also been measured, although the role of these currents in the mammalian auditory system remains to be properly understood. Two main types of outward potassium channel seem to be present in mammalian cochlear hair cells, voltage-gated (K_V) underlying slow potassium current (IKs in IHCs), and calcium-activated potassium channels. In OHCs, the latter seem to be further subdivided into two types, the A (or SK) type and the B type. Whereas an SK-like channel is expressed only in immature IHCs (Marcotti, W. *et al.*, 2004), the BK_{Ca} channel is present in mature IHCs and probably gives rise to a rapid outward current (Kros, C. J. *et al.*, 1998); deletion of the BK_{Ca} channels leads to progressive hearing loss including loss of the OHCs (Ruttiger, L. *et al.*, 2004), and a

relatively high level of mRNA for the gene is expressed in IHCs (Langer, P. *et al.*, 2003). Immunocytochemistry suggests that the channels are clustered around the neck of the IHCs as well as occurring in the synaptic region of both types of hair cell and possibly on the basolateral membrane of the OHCs (Pyott, S. J. *et al.*, 2004; Hafidi, A. *et al.*, 2005).

Deafness is also associated with a mutation in KCNQ4, a slow K_V channel which leads to progressive OHC degeneration (Kubisch, C. *et al.*, 1999). KCNQ4 is expressed in OHCs and, like BK_{Ca} echannels, shows a tonotopic gradient, increasing in density toward the high-frequency region of the cochlea (Mammano, F. and Ashmore, J. F., 1996; Ruttiger, L. *et al.*, 2004). Knockout of the BK_{Ca} channel also leads to loss of the KCNQ4 channel. The slow potassium currents may be associated with setting the resting potential, acting as a shunt to reduce potassium accumulation through the MET channels. Their tonotopic gradient may also reflect a contribution to reducing the membrane time constant and thereby improving high-frequency signaling at the basal end of the mammalian cochlea.

Inward voltage-dependent calcium currents have been detected in mouse hair cells (Engel, J. *et al.*, 2002), and data from a range of species suggest they are based primarily on L-type Ca^{2+} channels (Fuchs, P. A. *et al.*, 1990; Schnee, M. E. and Ricci, A. J., 2003). L-type Ca^{2+} channels have a basic subunit structure of α, β, $\alpha 2\delta$, and sometimes γ (Hille, B., 2001), but there is a range defined by differences in the α subunit. Mammalian hair cells from a knockout mouse for the α1D (now known as Ca(V)1.3) subunit show substantially reduced Ca^{2+} current (Platzer, J. *et al.*, 2000) and failure of afferent synaptic transmission in IHCs despite having a structurally intact synapse up to 4 weeks of age (Nemzou, N. R. M. *et al.*, 2006). *In situ* hybridization reveals a strong signal for Ca(V)1.3 (α1D) compared with a weaker signal for α1C (Kollmar, R. *et al.*, 1997).

Use of calcium-sensitive dyes suggests that there are calcium hotspots (regions of significant calcium concentration changes) in the basal pole of some auditory hair cells. Thus, these channels may be clustered in the vicinity of the synaptic contacts, providing calcium influx required for neurotransmitter release (Roberts, W. M. *et al.*, 1990; Issa, N. P. and Hudspeth, A. J., 1994; Tucker, T. and Fettiplace, R., 1995). Calcium influx is also likely to affect other properties of the hair cell through intracellular calcium-induced calcium release, and in OHCs, there may be an interaction between the Ca^{2+} channels and acetylcholine (ACh) channels located around the basal pole (Figure 4). The lateral membrane also contains calcium pumps but a different isoform from that present in the stereocilia, PMCA1b (Dumont, R. A. *et al.*, 2001). It is likely that these pumps interact with calcium channels and the local intracellular calcium stores and buffers to control synaptic modulation by calcium. In IHCs, this will regulate synaptic transmission elicited by mechanotransduction-induced depolarization, but their roles in OHCs may be more associated with modulation of the cell's motile activity since afferent synaptic activity by OHCs and its role remain to be established definitively.

The calcium pumps of the lateral membrane and buffers in the cytoplasm also play a role in efferent modulation of hair-cell function. In OHCs, nonmammalian auditory hair cells, and vestibular hair cells, there is modulation by efferents at the synaptic pole. The OHC efferent fibers largely use ACh as their neurotransmitter, although a subset of GABAergic fibers is also present. Accordingly, isolated OHCs respond to application of ACh by activation of an early inward current and a later outward potassium current ($I_{K(ACh)}$), both blocked reversibly by α-bungarotoxin. The inward current is probably carried partially by calcium which then activates calcium-sensitive potassium channels (Evans, M. G., 1996), presumably the BK_{Ca} channels mentioned earlier. This idea is supported by observations of calcium concentrations rising initially at the basal pole in response to ACh application but then spreading apically (Evans, M. G. *et al.*, 2000).

The properties of hair-cell ACh receptors are mixed, in that they show some characteristics that are nicotinic-like and muscarinic-like according to studies of different hair cells. In vestibular hair cells, muscarinic (metabotropic) and nicotinic (ionotropic) receptor agonists evoke different responses (see review by Guth, P. S. and Norris, C. H., 1996). However, the most consistent features suggest a nicotinic-like receptor that allows an influx of calcium. Earlier studies (Elgoyhen, A. B. *et al.*, 1994) suggested that this receptor may be composed of a novel subunit (α9), but subsequently, a second subunit type was identified (α10). From recombinant studies, the likely composition of hair-cell ACh receptors is a pentamer with an (α9)2(α10)3 stoichiometry (Plazas, P. V. *et al.*, 2005).

ACh thus acts on the hair cells directly to alter the membrane potential through ionotropic mechanisms (see review by Fuchs, P. A. and Parsons, T. D., 2006), but responses can be prolonged and may thus involve second messenger systems. In this case, it is thought

that as well as relatively fast ion channel responses, there is a slower response involving internal mobilization of calcium through calcium-induced calcium release. This process is discussed further below in relation to efferent modulation of OHC motility.

In addition to the synaptic structures, the OHCs of the mammalian cochlea have a structurally and compositionally specialized lateral wall which shares only partial similarity with IHCs but not other hair cells. This consists of the cortical lattice of the OHC and the plasma membrane which uniquely displays a substantial concentration of protein particles probably involved in these cells unique electromotile response (see below).

3.06.1.5 The Outer Hair Cell Lateral Wall

The lateral wall of the OHCs has received a lot of attention since it was discovered that these cells are electromotile – that is, they respond to both field potentials and microelectrode-generated depolarization–hyperpolarization cycles by cyclical contraction–elongation movements – and that this motility could underlie the cochlear amplifier. Both IHCs (Furness, D. N. and Hackney, C. M., 1990) and OHCs (Bannister, L. H. *et al.*, 1988) have a submembrane network called the cortical lattice that is bounded on one side by one or more layers of subsurface cisternae and on the other side by the plasma membrane (Figure 8).

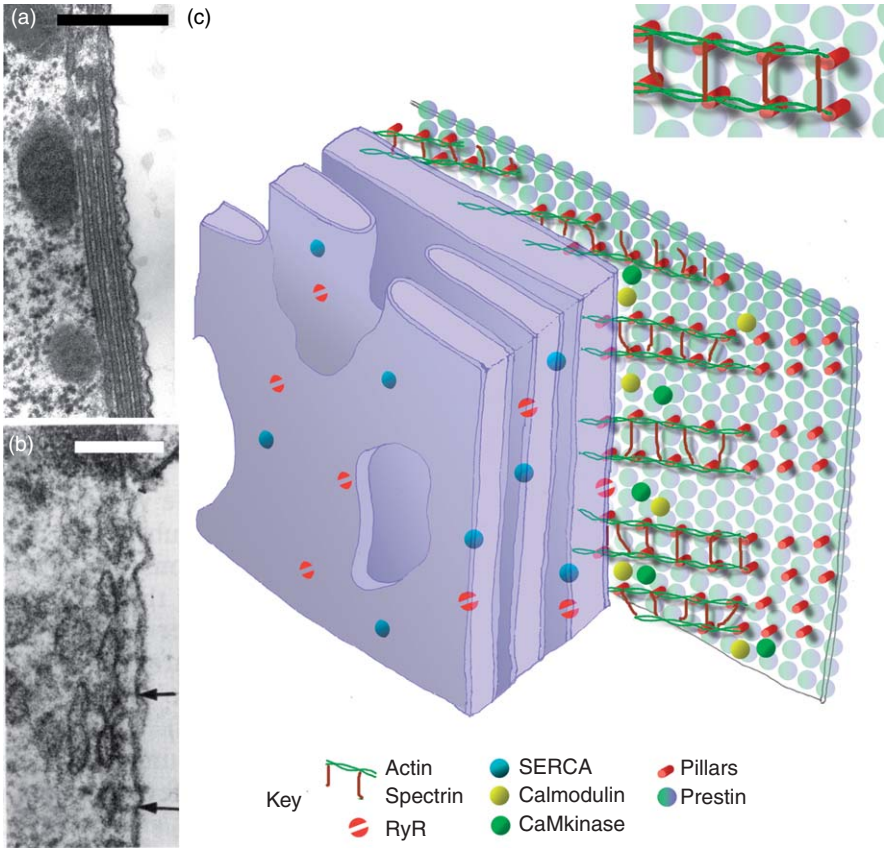

Figure 8 Lateral wall structures in an OHC. (a) Transmission electron micrograph showing the layers of membraneous cisternae and associated mitochondria. Scale bar = 500 nm. (b) Detail of the cortical lattice that lies between the plasma membrane and the first cisternal layer. Pillars connect the lattice with the membrane (arrows). Scale bar = 200 nm. (Adapted from Furness, D. N. and Hackney, C. M. 1985. Comparative ultrastructure of subsurface cisternae in inner and outer hair cells of the guinea pig cochlea. Eur. Arch. Otorhinolaryngol. 247, 12–15). (c) Schematic diagram of the cortical lattice and some associated molecules. The lattice is composed of actin filaments (primarily γ-actin) interconnected in tracks (as illustrated at higher magnification in the inset) by spectrin molecules. The lattice lies between the plasma membrane and the first cisternal layers and appears to be tied to the plasma membrane by pillars, the molecular composition of which has previously been suggested to be band 3 and protein 4.1R. Other molecules in the vicinity are calmodulin and CaM kinases which imply calcium-dependent process associated with the lattice. The cisternae contain other molecules involved in calcium-dependent processes such as ryanodine receptors and a calcium pump (SERCA).

Immunocytochemistry suggests that the lattice is composed predominantly of γ-actin filaments (Furness, D. N. *et al.*, 2005) and spectrin (Holley, M. C. and Ashmore, J. F., 1990; Mahendrasingam, S. *et al.*, 1998). The organization of this lattice has been studied by electron microscopy mainly in OHCs. Actin filaments in the lattice are preferentially circumferential in orientation and tend to occur in pairs (like railroad tracks) cross-linked by spectrin filaments (Holley, M. C. and Ashmore, J. F., 1990). Overlying the filament array and running along the tracks are pillar-like structures that extend up to the plasma membrane (Flock, A. *et al.*, 1986). Similar tracks and pillars have been observed in IHCs (Furness, D. N. and Hackney, C. M., 1990) and both actin and spectrin are localized there (Mahendrasingam, S. *et al.*, 1998; Furness, D. N. *et al.*, 2005).

The similarity of this lattice to that underlying the erythrocyte membrane has led to searches for similar proteins in OHCs. Thus, antibodies to band 3 and Protein 4.1 (now known as 4.1R and located also in stereocilia) have been used and labeling detected in the lateral wall of the hair cells, some of which could correspond to components of the lattice (Zine, A. and Schweitzer, L., 1997). Specific labeling of the pillars has yet to be clearly demonstrated so their composition remains uncertain. However, band 3 and protein 4.1R or related proteins could be associated with them. In erythrocytes, protein 4.1.R has multiple interactions with other lattice proteins, regulated by calcium and calmodulin, and is associated with stabilization of the membrane and cell shape (see review by Nunomura, W. and Takakuwa, Y., 2006); this could be a functionally relevant attribute in the OHCs.

In OHCs, freeze-fracture studies have shown that the plasma membrane adjacent to the lattice contains a high density of protein particles (Kalinec, F., *et al.*, 1992; Figures 4 and 8). These are thought to correspond to molecules of a protein called prestin, which is virtually unique to the OHC. Prestin, first reported by Zheng J. *et al.* (2000), is expressed throughout the basolateral membrane, though probably at a lower density in the synaptic region (Yu, N. *et al.*, 2006). It is believed to be a molecular motor that responds to voltage changes across the cell membrane by undergoing a conformational change. This in turn changes the area of the cell membrane and results in the elongation/contraction cycles that can be electrically evoked. Accordingly, the motility is reflected in nonlinear capacitance changes in the hair cells. There is also evidence of a higher density of the motor protein in freeze fractures of OHC membranes from high-frequency positions compared with low-frequency positions, which corresponds with gradients of motility-related charge along the cochlea (Santos-Sacchi, J. *et al.*, 1998).

Electromotility is absent in prestin-null mice, which also supports the notion that prestin is the motor that moves the OHC. However, the efficiency of this motor may be limited by the capacitance-filtering properties of the membrane which would reduce the effectiveness of the receptor potential in driving the prestin at the higher frequencies of mammalian hearing. Whilst this might be overcome by extracellular potential gradients driving the electromotility (Dallos, P. and Evans, B. N., 1995), another possibility is that an additional mechanism, perhaps related to bundle force generation (see above), may also be required; thus, there may be an interaction between hair bundle motility and somatic motility in cochlear amplification (Kennedy, H. J. *et al.*, 2006).

The subsurface cisternae (Figure 8) are membraneous compartments; only one layer is found in IHCs (Furness, D. N. and Hackney, C. M., 1990), but in OHCs, the number varies from 1 in hair cells near the basal end of the cochlea to between 10 and 20 apically in guinea pigs (Saito, K., 1983; Furness, D. N. and Hackney, C. M., 1990). In other species, such as bats, OHCs and IHCs also possess at least a single layer (Vater, M. *et al.*, 1992). It has been suggested that these cisternae are calcium stores and involved in calcium regulation of various cellular processes in OHCs. This could include motility of the lateral wall. Lim D. J. (1986) also suggests they have continuity with a single cisternal layer that lies adjacent to the membrane at the point of efferent contact, with the hair cell basal pole suggesting they may play a role in efferent modulation of the hair cell.

The relationship between the lattice, the prestin-based motor, and the cisternae and their role in calcium-dependent process is still being investigated. In rats, electromotility develops several days after prestin is first expressed at weak levels (Belyantseva, I. A. *et al.*, 2000) and simultaneously with the acquisition of calcium/calmodulin-sensitive motility dependent on the hair-cell cytoskeleton (Beurg, M. *et al.*, 2001). Specific localization of calmodulin (Nakazawa, K., 2001; Furness, Karkanavetos and Hackney, unpublished observations), CaMkinase (Koyama, M. *et al.*, 1999; Frolenkov, G. I. *et al.*, 2000), and protein phosphorylation cascade-IP(3) receptors (Frolenkov, G. I. *et al.*, 2000) along the lattice and adjacent subsurface cisternae suggests that it is a calcium-sensitive site with functions that could be

associated with second messenger-based modulation of the motility.

Belyantseva I. A. *et al.* (2000) argue that prestin expression and motility develop concurrently, but their data like those of Beurg M. *et al.* (2001) show an early dissociation in the time courses of the two that could reflect the deployment of components of the lattice. Thus, whilst the prestin may provide the motor, the lattice may be crucial for its efficient function within the cell.

The involvement of the cisternae in calcium-regulated processes is further supported by the presence of receptors for ryanodine (RyR – a molecule involved in calcium-induced calcium release) in them in both OHCs and IHCs. RyR are also found in a subset of rough endoplasmic reticulum located near the basal pole of the IHC (Grant, L. *et al.*, 2006). Ryanodine is involved in the response to ACh: the ryanodine receptor agonist caffeine initially facilitates the ACh response but then gradually suppresses it (Lioudyno, M. *et al.*, 2004). The latter authors suggest that the ryanodine receptors are localized to the subsynaptic cistern rather than the more distant subsurface cisternae. However, in rat cochleae, subsurface cisternae extend all the way round the basal pole of the hair cell up to the region of the efferent ending where they are briefly interrupted, so distances may not be so great (Furness, D. N., Mahendrasingam, S., and Hackney, C. M., unpublished observations) and continuity with the subsynaptic cistern could improve communication between these regions. Thus, it may well be that the subsurface cisternae and/or the subsynaptic cistern represent calcium stores and thus function in intracellular mobilization of calcium associated with efferent control.

The overall effect of efferent activation is to decrease cochlear sensitivity (see, e.g., Guinan, J. J. Jr. *et al*, 2005), but there are two different time courses, fast and slow. These presumably work by reducing the effective contribution of OHCs to the cochlear amplifier. The functional role of the efferent-based calcium mobilization is uncertain, as is the mechanism by which the amplifier is suppressed, because data obtained on OHC motility in response to ACh and calcium are somewhat contradictory. Ach-induced increased intracellular calcium can result in increased electromotility in a calmodulin-dependent manner, with a time constant of the order of 10 s (Dallos, P. *et al.*, 1997; Szonyi, M. *et al.*, 2001). Elevated intracellular calcium may also produce a long-term decrease in OHC axial stiffness (Frolenkov, G. I. *et al.*, 2003). Perhaps the decreased axial stiffness militates against the effectiveness of the increased motility and underlies the slow inhibition. These processes thus probably involve dynamic ACh-induced, calcium-dependent changes in the complex lattice and its linkage to the plasma membrane.

3.06.1.6 The Cytoplasm

In addition to the structural and functionally distinct regions already described, the remainder of the hair cell contains cytoplasmic components that include other molecules. Actin filaments and microtubules pervade the cytoplasm (Figures 2, 4, and 7). Microtubules are common in mammalian auditory hair cells (Furness, D. N. *et al.*, 1990; Steyger, P. S. *et al.*, 1991) and of the normal 13 protofilament variety, unlike the adjacent supporting cells (see below and Kikuchi, T. *et al.*, 1991). They are composed of βI and βII tubulin in IHCs and βI and βIV tubulin in OHCs (Jensen-Smith, H. C. *et al.*, 2003). In addition, the tubulin is tyrosinylated which makes the microtubules likely to be undergoing dynamic changes, again in contrast to those of the supporting cells (Slepecky, N. B. *et al.*, 1995; Bane, B. C., *et al.*, 2002). In both OHCs (Figure 4) and more prominently IHCs (Figure 7), the apical cuticular plate is surrounded by a basket of microtubules. These occur in a meshwork directly beneath the plate, in rings around the top and underside of the plate, and in the channel, presumably representing structural support for the apical MET apparatus. A basal body is found in all hair cells in the channel region or behind the rear of the cuticular plate, which in all except mammalian cochlear hair cells provides the base of the kinocilium. Microtubules extend down from the basal body region through the hair cell. In the IHCs, they form a prominent apico-basal track that probably constitutes a membrane trafficking path (Figures 2 and 7) between the apical endocytotic region described earlier and the basal synaptic pole (Steyger. P. S. *et al.*, 1989; Furness, D. N. *et al.*, 1990; Griesinger, C. B. *et al.*, 2002 – see Figures 2 and 7). They also enclose the projection of the cuticular plate found in long apical OHCs and encircle the circumference inside the membrane in the basal pole (Figure 4; Furness, D. N. *et al.*, 1990). Microtubules appear developmentally before the cuticular plate in some species (Heywood, P. *et al.*, 1975), indicating the possibility that they are involved in organizing some elements of the cytoskeleton.

Other vestibular and nonmammalian auditory hair cells probably contain similar microtubule patterns. There are apical concentrations and longitudinal tracks in rat vestibular hair cells (Jorgensen, J. M., 1982; Favre, D. and Sans, A., 1983), and longitudinally running microtubules have been described in chick (Cohen, G. M. and Fermin, C. D., 1978) and snake (Jorgensen, J. M., 1982) cochleae, ratfish lateral line (Ekstrom von Lubitz, D. K., 1981), and frog crista ampullaris (Flock, A. *et al.*, 1982).

Calcium-binding proteins including calbindin, calretinin, parvalbumin, and peptide 19 are found in hair cells (Imamura, S. and Adams, J. C., 1996; Hackney, C. M. *et al.*, 2003; 2005). Gradients of some of these proteins exist along the length of the mammalian cochlea, for example, calbindin appears to decrease toward the high-frequency region in mammals (Pack, A. K. and Slepecky, N. B., 1995) but increase in birds (Hiel, H. *et al.*, 2002). These discrepancies make determining the importance of buffers to the tonotopic variation in function difficult to evaluate. The role of intracellular calcium has already been discussed, and it is likely that these buffering proteins are associated with the precise control of calcium at different subcellular locations in the hair cell, for instance in modulating MET currents and adaptation, for modulation of the cytoskeleton involved in movements, both in the cytoplasm and the lateral wall of OHCs and in the synaptic region, where calcium regulates neurotransmitter release. There is a reduction in diffusible calcium buffers in mammalian IHCs during development in contrast to an increase to muscle-like levels in OHCs which suggests that calcium ions may play different roles in these two types of hair cells (Hackney, C. M. *et al.*, 2005).

3.06.1.7 Supporting Cells

The supporting cells of auditory epithelia surround the hair cells and in all except the mammalian organ of Corti completely enclose their basolateral regions. The base of each OHC is supported by a Deiters' cell cup and the apex by the process of a nearby Deiters' cell; each IHC is supported by inner phalangeal cells (Figure 9) and border cells. Between the IHC and first OHC rows, there are two rows of pillar cells, the inner and the outer. The supporting cells are characteristically shaped to support the hair cells mechanically within the epithelium, but they also assist in providing homeostatic support in a variety of ways for the various processes that occur in hair cells.

In the mammalian cochlea, the inner and outer pillar cells (IPC and OPC) both contain a rod-like process, filled with microtubules and actin filaments that extend up from a basal foot resting upon the basilar membrane to a head region (Figure 9). The foot and the head contain an anchoring mat of actin filaments composed of both β- and γ-actin and similar in appearance to the hair-cell cuticular plate. The head region has a second process extending across the organ of Corti radially, that of the IPC overlying the head of the OPC, whilst that of the OPC surfaces between the OHCs of the first row (Figure 2).

Compared with the cuticular plate of the hair cell, the actin-rich mats in the pillar cell apices contain approximately 10× (in IPC) to 20× (in OPC) the concentration of β-actin and about half the concentration of γ-actin. There is a greater overall concentration of actin which means that the actin filaments are probably more densely packed. Furthermore, the outer pillar cells have a higher proportion of β-actin in high-frequency regions compared with low-frequency regions, at least in guinea pig (Furness, D. N. *et al.*, 2005). The number of microtubules in the pillar cells also changes systematically, increasing toward the basal end of the cochlear spiral (Kikuchi, T. *et al.*, 1991). In addition, the pillar bundles contain tropomyosin, which could be associated with added stiffness (Slepecky, N. and Chamberlain, S. C., 1987). These high concentrations of significant cytoskeletal proteins indicate the importance of mechanical strengthening in the mammalian organ of Corti. There is little evidence of similar strut-like bundles in supporting cells of other auditory or vestibular epithelia.

Similar, but smaller, microtubule and actin bundles, also containing tropomyosin, occur in the other main supporting-cell type of the organ of Corti, the Deiters' cell (Slepecky, N. and Chamberlain, S. C., 1985; Slepecky, N. B. and Chamberlain, S. C., 1987; Steyger, P. S. *et al.*, 1989). Each Deiters' cell has a cylindrical body sitting with its base on the basilar membrane and reaching up to the bottom of the OHC above it. At this point, the Deiters' cell supports the synaptic pole and the incoming fibers of the OHC in a cup. The cup is rich in microtubules (Steyger, P. S. *et al.*, 1989; Furness, D. N. *et al.*, 1990), and actin filaments of both β- and γ-actin isoforms lie beneath the membrane directly opposed to the hair-cell base (Furness, D. N. *et al.*, 2005). Emanating from the strial side of the Deiters' cell body is a phalangeal process which also contains a microtubular and actin bundle (Figure 9). This process stretches up to the surface of

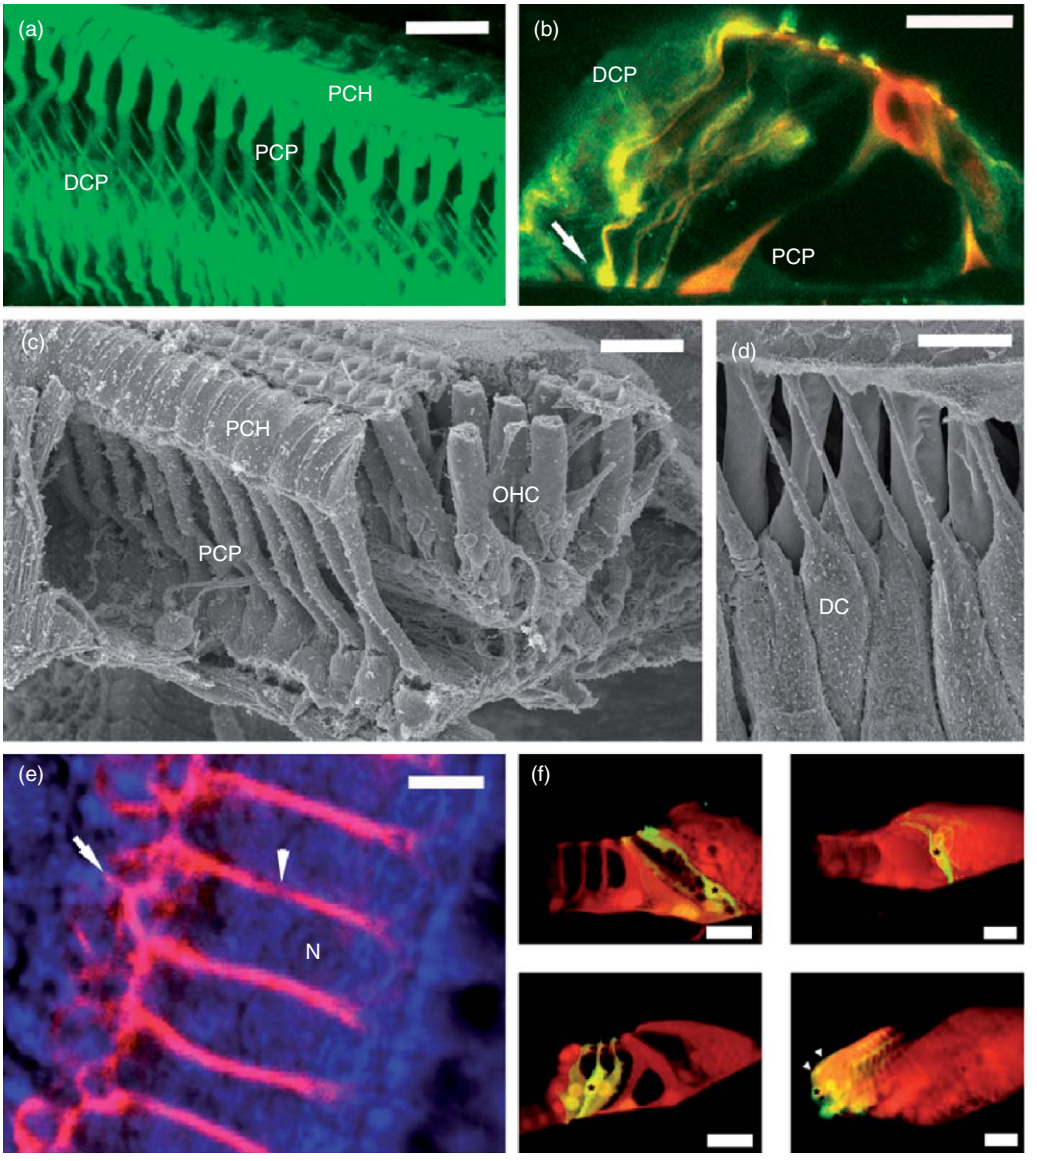

Figure 9 Structure and composition of supporting cells. (a) Deiters' cells and pillar cells labeled with tubulin antibodies and imaged using a confocal microscope. The microtubular bundles of the pillar cell processes (PCP) reach up to the pillar cell heads (PCH) and the thinner phalangeal processes of the Deiters' cells to their respective apical portions (DCP). Scale bar = 20 μm. (b) Cross section of the organ of Corti double labeled for β-actin (red) and γ-actin (green). Note colocalization (yellow-orange) in the Deiters' cell (DCP) and pillar cell (PCP) processes, especially in the former. The foot of both processes lies directly over the basilar membrane (indicated by an arrow for the DCP). The pillar cells have relatively more β-actin, as indicated by their redder coloration. Scale bar = 10 μm. (c) Scanning electron microscopy of a fracture of the organ of Corti showing the rod-like PCP culminating in the apical head (PCH). The OHCs are shown for orientation. Scale bar = 10 μm. (d) Scanning electron micrograph of Deiters' cells (DC) showing the cell bodies and thin phalangeal processes emanating obliquely from them. Scale bar = 10 μm. (e) Combined bright field (blue) and confocal fluorescent image (red) showing labeling for the glutamate transporter GLAST in mouse inner phalangeal cells around the IHCs which cup the IHC (identified by its central nucleus (N)) and send processes out to wrap incoming afferent nerves at the synaptic pole (arrow). Scale bar = 10 μm. (f) Demonstration of gap junctional coupling between supporting cells at postnatal day 8 (prior to the onset of hearing). Yellow represents Lucifer Yellow and red neurobiotin. Top panels show an inner phalangeal cell injected with both dyes but transfer only of neurobiotin to other supporting cells. Bottom panels illustrate Deiters' cells showing transfer of both dyes at this age. Scale bar = 20 μm. Reproduced, with permission, from Jagger, D. J. and Forge, A. 2006. Compartmentalized and signal-selective gap junctional coupling in the hearing cochlea. J. Neurosci. 26, 1260–1268, Copyright 2006 by the Society for Neuroscience.

the organ of Corti (called the reticular lamina) where it spreads to form a plate connected to the adjacent hair cells via junctional complexes. The microtubular-actin bundle approaches the complex but ends in a substantial mat of actin filaments prior to the junction. This mat contains intermediate amounts of β- and γ-actin between the cuticular plate of the hair cell and the head of the pillar cells (Furness, D. N. *et al.*, 2005).

As well as being rich in actin and tubulin, all mammalian cochlear supporting cells have a substantial cortical lattice containing spectrin and microfilaments (Mahendrasingam, S. *et al.*, 1998). This lattice does not appear to have the same systematic organization as found in the hair cells but presumably confers some elasticity on the periphery of the supporting cell, which is likely to prevent disruption of the cells in the mechanically active organ of Corti. They also express glial fibrillary acid protein (GFAP – Rio, C. *et al.*, 2002) which is characteristic of some glia, including astrocytes and nonmyelinating Schwann cells in the central nervous system, which implies functional similarity with glia.

The concentration of cytoskeletal proteins in these cells is consistent with the notion that one of their main functions is mechanical support. The extent to which this support is purely passive or actively modulated and able to change the mechanical properties of the organ of Corti is uncertain. As shall be seen below, some of the supporting cells possess ion channels and receptor molecules associated with possible homeostatic and modulatory functions and some may be innervated. The stalks of Deiters' cells can be induced to move by ATP (Bobbin, R. P., 2001), which suggests that they may have more than a passive role in cochlear mechanics.

The cells also express a number of proteins involved in homeostasis; inner phalangeal, border, and Deiters' cells express a major brain protein, the glutamate transporter, GLAST (Furness, D. N. and Lehre, K. P., 1997; Furness, D. N. *et al.*, 2002a). In astrocytes, GLAST functions in maintaining low extracellular levels of glutamate around glutamatergic synapses.

Deiters' cells contain a relatively low concentration of GLAST, and apical Deiters' cells express more GLAST than basal ones (Furness, D. N. *et al.*, 2002a; 2000b). This matches the pattern of afferent (presumptive glutamatergic) synapses to the OHCs and which suggests that they may release glutamate synaptically. The supporting cells around the IHCs, the inner phalangeal cells and border cells, in effect cup the IHC completely, except for its apical end. Both cell types express significant amounts of GLAST (Figure 9; Furness, D. N. and Lehre, K. P., 1997) with enrichment in finger-like processes around the nerve endings. These cells too show a cochleotopic gradient that matches the number of afferent endings on the IHCs which vary systematically along the cochlea (Furness, D. N. and Lawton, D. M., 2003). It is likely that GLAST here serves to take up glutamate from the synaptic clefts and surrounding extracellular space to help shape glutamate receptor activity in the afferent synapses and reduce the potential for excitotoxic damage to afferent terminals (Furness, D. N. and Lehre, K. P., 1997). GLAST knockout mice have no hearing defects but an enhanced susceptibility to trauma and elevated glutamate levels in cochlear fluids (Hakuba, N. *et al.*, 2000). The presence of GLAST thus seems likely to be a major player in glutamate homeostasis, especially associated with the primary receptor function of IHCs.

Supporting cells also express various calcium buffers although at lower levels than in hair cells. Thus, a low concentration of calretinin is present in Deiters' cells (Pack, A. K. and Slepecky, N. B., 1995; Hackney, C. M. *et al.*, 2005) and supporting cells of other vertebrates, such as turtles (Hackney, C. M. *et al.*, 2003). Another calcium-binding protein present in supporting cells is S-100 (Pack, A. K. and Slepecky, N. B., 1995). There is also expression of PMCA1b in the plasma membrane (Dumont, R. A. *et al.*, 2001).

Another common feature of the supporting cells seems to be the presence of gap junctions. These have been elegantly demonstrated in intracellular dye marking experiments with neurobiotin and Lucifer Yellow injected into individual supporting cells in cochlear slices from rats during development (Figure 9). Intracellular fluorescent neurobiotin (Jagger, D. J. and Forge, A., 2006) injected at postnatal day 12 (after the onset of hearing) spreads from one supporting cell to neighboring supporting cells in all directions (pillar cells, Deiters' cells, and inner phalangeal/border cells), indicating they have gap junctions containing connexin 30 only or connexin 30/26. However, dye injected into IPC does not transfer to outer pillar cells or vice versa. Injections of Lucifer Yellow (a marker for connexin 26-only gap junctions) are restricted in their spread at that age. Immunocytochemical data also suggested some colocalization of the two connexins, suggesting that gap junctions of either monomeric connexin 30 or heteromeric connexin 26/30 couple supporting cells together. The spread of Lucifer Yellow at postnatal

day 8 prior to the onset of hearing is wider (Figure 9), indicating a change in the gap junction distribution during maturation to the more restricted adult pattern, which it is suggested ultimately produces separate buffering compartments for IHCs and OHCs in the hearing cochlea (Jagger, D. J. and Forge, A., 2006). The significance of these findings relates to deafness genes which show that defects in both connexins result in hearing loss. The role of these junctions has been proposed to be in K^+ homeostasis, the supporting cells able to act as a passive sink for potassium.

A number of ion channels are expressed in supporting cells. $P2X_2$ (Housley, G. D. *et al.*, 1999) and P2y (Housley, G. D. *et al.*, 2006) receptors are found in the basolateral regions of Deiters' cells and pillar cells, as well as in other cells of the organ of Corti. The purinergic receptors presumably are involved in these cells' motile response to ATP (Bobbin, R. P., 2001). They also contain mRNA for voltage-insensitive potassium channels TASK-1 and TREK-1 (Kanjhan, R. *et al.*, 2004). Two possible types of voltage-sensitive outwardly rectifying potassium channels have been detected physiologically in Deiters' cells (Szucs, A. *et al.*, 2006). Finally, the water channel aquaporin 4 has been detected in Deiters' cells and inner phalangeal/border cells (Mhatre, A. N. *et al.*, 2002; Miyabe, Y. *et al.*, 2002).

Apart from their contribution to mechanics, the most likely role of supporting cells in the cochlea, therefore, is in homeostatic support for the hair cells. The presence of ion channels and gap junctions, the glutamate transporters, and water channels is likely to reflect control of the environment, particularly around the IHCs and OHCs.

Finally, mention should also be made of the innervation of supporting cells. There have been reports of synaptic structures onto some Hensen's and Deiters' cells (Burgess, B. J. *et al.*, 1997) and some evidence that they respond to ACh via an ACh receptor (Matsunobu, T. *et al.*, 2001). Whether this innervation has a functional role in cochlear mechanics or homeostasis remains to be determined.

3.06.1.8 Concluding Remarks

This review has attempted to draw together a large body of work to illustrate the complex molecular architectures of hair cells and supporting cells which together give the auditory epithelium its ability to perform mechanotransduction of acoustic signals, giving animals a highly sensitive and accurate auditory system. During evolution, the sensitivity, frequency selectivity, and dynamic range of auditory organs have been extended. To achieve this, a number of unique proteins and highly specialized molecular arrangements have also evolved – these include the mammalian motor protein, prestin, and the cortical lattice. Despite their specialization, mammalian hair cells share fundamental properties with all hair cells and the field still holds the potential for many interesting surprises – for example, mechanisms of amplification only recently being considered in mammalian hair bundles were first described more than 20 years ago in nonmammalian hair cells. The MET mechanism and the MET channel itself seem to be common to all hair cells, at least in its underlying principles, yet a proper understanding of the gating mechanism and the identity of the channel is still being sought.

Throughout this review, we have attempted to provide a description of the molecular composition of cells in the organ of Corti, but we have drawn on data from other species where relevant. However, there are many molecules that have not been discussed; apart from the basic molecules that are common to most or all eukaryotic cells, there are transient molecules, developmental regulators, and signaling molecules that shape the cells and the epithelium in which they lie, and there are most certainly interesting and potentially unique molecules as yet undiscovered. Some of the molecules we may have omitted or discussed only briefly may turn out to be crucial in terms of hearing and deafness, whilst others that are currently hot topics may turn out to be less important as their roles become better understood.

Glossary

codon A set of three bases that specifies a single amino acid or signals the termination of the amino acid sequence.

compound heterozygote An individual with a recessive disorder who has a different mutation in the two copies of the gene (cf., homozygote).

cryptic splice site A DNA sequence that is similar to a consensus splice site sequence but is not usually used unless there is a mutation in the normal splice site, or a mutation in the cryptic splice site results in it being preferred over the normal splice site.

dominant negative The abnormal product of a mutant copy of a gene disrupts the function of the product of the normal copy of the gene.

exon Segment of a gene that is transcribed and present in mature mRNA.

founder effect A mutation that is present in a small ancestral population, which increases in frequency by chance due to the initial small population size.

frameshift mutation An insertion or deletion of a number of base pairs that is not a multiple of three, and therefore changes the codons that follow.

genome The complete DNA sequence. For example, the nuclear genome of a human germ cell (sperm or ovum) consists of 3 million kb of DNA.

genotype The two copies of the gene (one of each chromosome) that are present at a locus.

haploinsufficiency The product of the normal copy of a gene is not adequate to prevent the disease when the mutant copy of the gene does not have a functional product.

heterozygote An individual whose genotype consists of two different copies of the gene.

homozygote An individual whose genotype consists of two identical copies of the gene.

intron Segment of a gene that is not present in the mature mRNA.

isoform Alternate forms of a protein.

kilobase (kb) A unit of 1000 bases in a DNA sequence.

linkage A statistical method of analysis of family phenotype and genotype data that provides the probability that two or more loci are not assorting independently (i.e., they are linked).

locus The position of a gene on a chromosome.
messenger RNA (mRNA) An RNA transcribed from the DNA of a gene, which directs the sequence in which amino acids are added to the product encoded by that gene.
missense mutation A substitution of one base by another such that the amino acid specified by the codon is changed.
modifier gene A gene that alters the phenotype associated with mutations in another gene.
nonsense mutation A substitution of one base by another such that the resulting codon specifies termination of the amino acid sequence.
penetrance The probability that a given genotype will result in a particular phenotype.
phenocopy A phenotype that looks the same as one produced by a specific genotype, but has a different etiology.
phenotype The observed characteristics of an individual.
splice site The DNA sequence that specifies the boundary between an intron and an exon in a gene. The introns are removed in the generation of the mature mRNA.
stop codon One of three codons specifying the termination of the product encoded by a gene.
transcription The synthesis of a single-stranded mRNA molecule (transcript) from a DNA template.
translation The synthesis of a sequence of amino acids from the mature mRNA template.

3.07.1 Introduction

The human genome contains about 30 000 genes, and mutations in the DNA sequences of more than 100 of these genes are associated with hearing loss. The degree of genetic hearing loss may range from mild to profound and some frequencies may be affected more than others; for most individuals the loss is sensorineural, bilateral, and symmetric. Onset is often congenital (present at birth), but it can be later in childhood or in adulthood. Many different genetic forms of hearing loss may give similar pure tone air conduction audiograms. Thus, ideally, a battery of physiological measurements that include tympanometry, middle ear muscle reflexes, otoacoustic emissions (OAEs), speech audiometry, and auditory brainstem response/electrocochleography (ABR/EcochG) should be obtained for each patient in order to categorize the hearing loss accurately and determine the most effective management (Keats, B. J. B. and Berlin, C. I., 2002).

About 30% of genetic hearing loss is syndromic, meaning that there are associated abnormalities in other organs such as the eye (Usher syndrome), kidney (Alport syndrome), skin (Waardenburg syndrome), heart (Jervell and Lange-Nielsen syndrome), and thyroid (Pendred syndrome). For the remaining 70%, the hearing loss is nonsyndromic. Griffith A. and Friedman T. (2002) and Toriello H. V. *et al.* (2004) provide comprehensive descriptions of syndromic and nonsyndromic hearing loss.

The mode of inheritance of hearing loss in a family may be dominant or recessive, and the mutation may be in a gene on one of the autosomes (chromosomes 1–22) or on the X-chromosome; these chromosomes are in the nucleus of the cell. A pedigree showing who is affected and who is unaffected in the family helps to determine the inheritance pattern. Figure 1 shows an example of autosomal dominant inheritance in which individuals with one normal

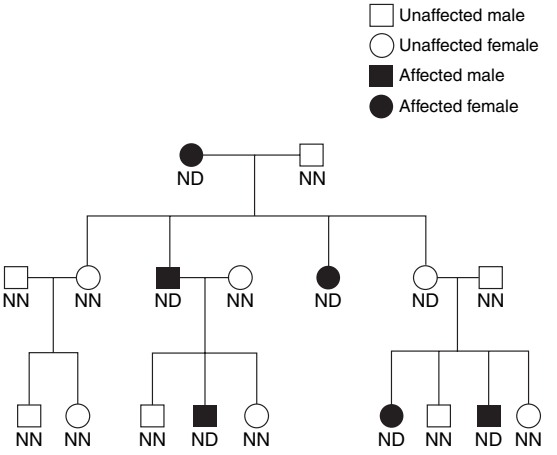

Figure 1 A pedigree showing an autosomal-dominant pattern of inheritance with incomplete penetrance. N is the normal form of the gene and D is the abnormal (mutant) form of the gene. Individuals with the NN genotype are unaffected and those with the ND genotype are expected to be affected. However, the sixth individual in the middle generation is unaffected but has an affected mother and two affected children. Thus, her genotype must be ND. This is an example of incomplete penetrance meaning that for individuals with the ND genotype, the probability of being affected is less than 1.

copy (N) and one abnormal copy (D) of the gene are usually affected; their genotype is ND and each of their offspring has a 50% chance of inheriting the D. However, the phenotype may be variable, and penetrance may be incomplete, meaning that some ND individuals may show no signs of being affected. The hearing loss is autosomal recessive if only individuals with the DD genotype are affected. Those with the ND genotype are unaffected and are referred to as carriers (or heterozygotes). Each offspring of two carrier parents has a 25% chance of inheriting the DD genotype and being affected. Family history is quite likely to be negative for a child with autosomal recessive hearing loss. Conversely, both parents may have autosomal recessive hearing loss but all their children may have normal hearing because mutations in different genes are responsible for the hearing loss in the parents. If all the affected individuals in a pedigree are male, and none of the affected males have affected sons, then the inheritance pattern is likely to be X-linked recessive. In this case, each son of a carrier mother has a 50% chance of being affected and all the daughters of an affected male will be carriers.

The symbols, DFNA*, DFNB*, and DFN*, are used to designate autosomal dominant, autosomal recessive, and X-linked hearing loss, respectively, where the asterisk represents a number. The symbol is assigned when the chromosomal location of the hearing loss gene is determined, usually through genetic linkage analysis. For example, DFNB21 means the twenty-first autosomal recessive locus mapped. When the abnormal gene at the locus is identified, a gene symbol is assigned. For human genes, the symbol is written in uppercase and italics. As a generalization, recessive hearing losses tend to be prelingual while dominant forms are postlingual and progressive, but there are exceptions. In some families the phenotype may vary from one affected child to another. Such findings may be examples of variable expression, but the possibility of phenocopies must be considered.

As well as the DNA in the nucleus, each of the several hundred mitochondria in a cell have multiple copies of their own DNA, and some forms of hearing loss are associated with mutations in this mitochondrial genome (mtDNA). Quite often the mutation is present in some copies of the mtDNA, but not others, a condition known as heteroplasmy. The number of base pairs of mtDNA is only about 16 000 compared with the three billion in the nuclear genome. Mitochondria are maternally inherited, so the pattern of inheritance is likely to be mitochondrial if all the offspring of an affected mother (but none of those of an affected father) are affected. However, because of heteroplasmy, the severity of the phenotype among the offspring may vary considerably. The majority of genetic hearing loss is autosomal recessive, but about 20% is autosomal dominant and 1–2% is X-linked or mitochondrial.

Throughout the body, the set of genes that are expressed varies among cell types, and from one stage of development to another. The characteristics of genetic forms of hearing loss are likely to differ depending on the cellular and subcellular localizations, and the functions of the proteins encoded by the associated genes. These proteins must be essential for normal hearing. They include cytoskeletal proteins, extracellular matrix proteins, transcription factors, and proteins required for ion homeostasis.

Because of the similarity between the mouse and human genomes, studies of mouse models are often quite informative in advancing understanding of genetic hearing loss. Many of the available mouse models are the result of spontaneous mutations, while others have been created using transgenic or gene knockout experimental approaches. The symbols for mouse genes are written in lowercase to differentiate them from human genes.

This perspective will focus on four genes (*USH1C*, *GJB2*, *OTOF*, and *TECTA*) that are associated with hearing loss and typify the range of phenotypes and modes of inheritance. They encode the proteins harmonin, connexin 26, otoferlin, and α-tectorin, which are expressed in four different cellular/subcellular locations in the inner ear and have diverse functions. Harmonin and otoferlin are cytoskeletal proteins, while connexin 26 is critical for maintaining ion homeostasis in the cochlear duct, and α-tectorin is an extracellular matrix protein that is an essential component of the tectorial membrane. Both dominant and recessive inheritance patterns have been found in families with mutations in *GJB2* and *TECTA*, while mutations in *GJB2* and *USH1C* are associated with both syndromic and nonsyndromic hearing loss, and mutations in *OTOF* have been found in children with auditory neuropathy/auditory dyssynchrony (AN/AD).

3.07.2 USH1C

Usher syndrome is clinically and genetically heterogeneous. Three clinical types have been described

based on the degree of hearing loss, vestibular function, and age of onset of retinal degeneration. Usher syndrome type I is the most severe, with profound hearing loss from birth, abnormal vestibular function, and retinal degeneration beginning with night blindness by the end of the first decade. As many as 6% of children born with profound hearing loss may have Usher syndrome type I. The pattern of inheritance is autosomal recessive, and mutations in at least six different genes are associated with Usher syndrome type I (Keats, B. J. B. and Savas, S., 2004). One of these genes is *USH1C*. It was mapped to the short arm of chromosome 11 in families of Acadian ancestry in south Louisiana. The original Acadians were French fishermen who left France in the early 1600s and settled in the Nova Scotia region (Acadia) of Canada. Their population size expanded dramatically until 1755 when they were forced to leave Canada. Over the next 40 years about 3000 Acadians moved to south Louisiana. Today more than 600 000 Louisiana residents consider themselves to be Acadians, and the frequency of Usher syndrome type IC is significantly higher than in any other population.

In 2000, the *USH1C* gene was identified and shown to encode a PDZ domain-containing cytoskeletal protein known as harmonin (Bitner-Glindzicz, M. *et al.*, 2000; Verpy, E. *et al.*, 2000). One mutation is specific to the Acadian population probably due to founder effect, but several others have been reported in different populations and some are associated with autosomal recessive nonsyndromic hearing loss (DFNB18) rather than Usher syndrome.

3.07.2.1 Structure, Expression, and Function

The *USH1C* gene contains 28 coding exons spanning approximately 50 kb of genomic DNA. As a result of alternative splicing of eight exons, multiple isoforms that are divided into three classes (a, b, c) are found. They vary in size from approximately 400 to 900 amino acids. Both a and b isoforms contain three PDZ domains while c isoforms have only two. The b isoforms are the longest and use exons that are not translated in either of the two shorter isoforms. The human and mouse proteins are 96% identical.

USH1C transcripts are present in many tissues, including colon, small intestine, kidney, brain, muscle, heart, and pancreas, in addition to the ear, eye, and vestibule. In the ear and eye, *USH1C* is expressed in the stereocilia of the hair cells and the photoreceptor cell synapses (Reiners, J. *et al.*, 2003). Isoforms a and c are widely expressed, but the longest isoforms (b) are found mostly in the stereocilia of the vestibular and cochlear hair cells. Developmental expression studies in mice detected harmonin b in the stereocilia from E15 until P30, suggesting that it is important for the development of the hair bundle (Boeda, B. *et al.*, 2002).

PDZ domain-containing proteins act as adapters for organizing protein complexes that usually involve transmembrane proteins. The protein products of other Usher type I genes (myosin VIIa, cadherin 23, protocadherin 15, and sans) cluster with harmonin via the first PDZ domain. This clustering, together with the localization of these proteins to the synaptic regions of the hair cells and photoreceptor cells, suggests this protein network may be involved in the organization or function of hair cell and photoreceptor cell synapses (Adato, A. *et al.*, 2005).

3.07.2.2 Mutations

Mutations in *USH1C* that are associated with Usher syndrome type IC include two frameshift mutations (insertions), four splice site mutations, and a nonsense mutation. All of these mutations are expected to result in a severely truncated transcript and no protein product. The causal mutation in Acadian Usher IC patients is a substitution (216G→A) that introduces a cryptic splice site in exon 3 and results in the deletion of 35 bases in the mature messenger RNA (mRNA; Lentz, J. *et al.*, 2005). The most common *USH1C* mutation, 238–239insC in exon 3, has been found in several different populations (Zwaenepoel, I. *et al.*, 2001).

The ability to diagnose Usher syndrome early enables appropriate management and provides time for the development of communication skills that do not rely on vision. In particular, an Acadian child with profound sensorineural hearing loss should be tested for the 216G→A mutation to determine if the correct diagnosis is actually Usher syndrome type IC.

Some mutations in *USH1C* are associated with hearing loss but not retinal degeneration. Because the b isoforms of harmonin are expressed at high levels only in the inner ear, and use some exons that are not translated in isoforms a and c, mutations in these exons would be predicted to cause nonsyndromic hearing loss. In fact, Ouyang X. *et al.* (2002) found four missense mutations in exons B and D, which are used only in isoform b, in patients with nonsyndromic hearing loss (DFNB18).

In contrast, Ahmed Z. M. *et al.* (2002) reported members of an Indian family with nonsyndromic hearing loss who were homozygous for a splice site mutation (IVS12+5G→C) in *USH1C*. *In vitro* studies showed that the presence of this mutation resulted in a mixture of both normal and aberrantly spliced mRNA. It is unlikely that the abnormal transcript forms a protein product; thus, the amount of harmonin that is produced must be adequate for normal retinal function, but not enough to preserve the cochlear hair cells.

3.07.2.3 Mouse Models

The deaf circler (*dfcr*) and deaf circler 2 Jackson (*dfcr 2J*) mice have spontaneous mutations in the *USH1C* gene and as with other mouse models for Usher syndrome type I, the stereocilia are disorganized (Johnson, K. R. *et al.*, 2003). However, the mouse models do not develop retinitis pigmentosa. The *dfcr* mutation is a large deletion that includes several exons, but does not change the reading frame, while the *dfcr 2J* mutation is a one base deletion in exon C. Only harmonin b is affected in *dfcr 2J*, but all isoforms are expected to be abnormal in *dfcr*.

ABR testing demonstrated that both *dfcr* and *dfcr 2J* mice were completely deaf (no response at 100 dB sound pressure level), and scanning electron microscopy revealed disorganized stereocilia by 3 weeks of age. A slight peripheral retinal degeneration was observed in three *dfcr* mice at 9 months of age, but electroretinograms (ERGs) were normal.

3.07.3 GJB2

Linkage analysis of two consanguineous families from Tunisia localized the DFNB1 locus to chromosome 13q12. The *GJB2* (Gap Junction Protein Beta 2) gene had been mapped to the same location, and Kelsell D. P. *et al.* (1997) identified mutations in this gene in children with nonsyndromic recessive deafness. The phenotype is usually severe-to-profound congenital hearing loss, but it may be mild-to-moderate and progressive. Although not common, syndromic (usually associated with skin abnormalities) and nonsyndromic (DFNA3) autosomal dominant families have been described with mutations in *GJB2*. In some populations, *GJB2* mutations explain as much as 50% of autosomal recessive hearing loss. Pandya A. *et al.* (2003) estimated that, on average, *GJB2* mutations account for about 22% of hearing loss in children, but pointed out that the percentages differ significantly among ethnic groups.

3.07.3.1 Structure, Expression, and Function

The *GJB2* gene consists of two exons, with exon 2 encoding the 208 amino acid protein. Exon 1 is not translated. The promoter region of the mouse and human genes is highly conserved, and includes GC boxes, GT boxes, and a TTAAAA box (Kiang, D. T. *et al.*, 1997). Because of the relatively short coding sequence, identification of mutations by sequencing is efficient and often provides a definitive diagnosis.

GJB2 is expressed in many tissues, including skin, liver, breast, bladder, and pancreas. In the inner ear, *GJB2* is expressed in both the epithelial and the connective cellular networks. These include the supporting cells of the hair cells, as well as the spiral limbus, spiral ligament, and stria vascularis.

The protein encoded by *GJB2* is usually called connexin 26. There are 20 different types of human connexins; two of these (connexin 26 and connexin 30) co-localize in the cochlea (Marziano, N. K. *et al.*, 2003). Each connexin consists of four transmembrane domains connected by one intracellular loop, two extracellular loops, and cytoplasmic N and C terminals. Connexons, which are comprised of six connexins, join with those in an adjacent cell to form homotypic, heterotypic, or heteromeric channels between the cells. The connexons are formed intracellularly and are trafficked to the plasma membrane. These gap junctions allow intercellular diffusion of small molecules and metabolites with a molecular mass up to about 1 kDa. The turnover time of connexins is very rapid, indicating that gap junction channels are replaced several times every day. They are thought to be important for maintaining high concentrations of K^+ in the endolymph via recycling from the perilymph. In turn, this recycling is necessary for the maintenance of the endocochlear potential, which is essential for normal auditory function. Normal forms of both connexin 26 and connexin 30 appear to be required for formation of functional gap junction channels in the support cells of the cochlea, indicating that they do not functionally compensate for one another (Ahmad, S. *et al.*, 2003).

3.07.3.2 Mutations

More than 90 different mutations have been reported in exon 2, the most common in the Caucasian

population (particularly those from southern Europe) being 35delG with a carrier frequency of about 2%. This deletion of a guanine in codon 12 means that codon 13 becomes a stop codon, and translation is terminated. Other mutations have been reported with increased frequencies in particular populations, such as 167delT and 235delC in the Ashkenazi Jewish and Asian populations, respectively.

Although most of the mutations in *GJB2* are associated with recessive hearing loss, some have been found in families with dominant hearing loss (DFNA3). All are missense mutations and for a few, the phenotype is syndromic with skin abnormalities in addition to the hearing loss.

Many variants that do not segregate with hearing loss have been reported. The M34T allele is controversial. Individuals with normal hearing based on pure-tone audiograms and 167delT/M34T and 35delG/M34T genotypes have been reported, but other studies suggest that M34T contributes to recessive mild-to-moderate- or high-frequency hearing loss.

Often, interpretation of diagnostic test results is not straight forward because only one mutation is found. Several explanations are possible: the second mutation may have been missed or the individual may be a carrier (by chance), with the hearing loss having nothing to do with the mutation. In some cases, it has been shown that the second mutation is a 309 kb deletion or a 232 kb deletion that encompasses all or part of the *GJB6* gene, which encodes connexin 30 (del Castillo, F. J. *et al.*, 2005). *GJB2* and *GJB6* are less than 50 kb apart, and share 77% identity in amino acid sequence, with connexin 30 having 37 more amino acids at its C-terminus than connexin 26.

The nonsyndromic recessive phenotype can vary from mild to profound hearing loss, even in individuals with the same *GJB2* mutations. This finding suggests that modifier genes may be involved, but a systematic study to find such genes has not yet been done.

3.07.3.3 Mouse Models

The knockout mouse is an embryonic lethal, but studies of conditional knockout mice suggest that interference with potassium recycling may explain the hearing loss that results when connexin 26 is missing in the inner ear (Cohen-Salmon, M. *et al.*, 2002). Mice do not hear until about 2 weeks after birth and the inner ears of the mutant mice were found to develop normally until P14 when apoptotic cell death began to occur. Supporting cells of the inner hair cells were the first to die, followed by outer hair cells and their supporting cells. However, the inner hair cells were generally preserved, although ultrastructural analysis revealed anomalies. The mice showed a significant hearing loss with an average of 30 dB at 8 kHz to 36 dB at 32 kHz relative to heterozygous and control mice. The endocochlear potential in adult mutants was significantly lower than in control mice as was the K^+ concentration in the endolymph. In contrast, the mutant mice did not show any vestibular dysfunction, suggesting that connexin 26 is not required for normal function of gap junctions in the vestibular system. Additionally, connexin 30 expression was not affected by the absence of connexin 26.

3.07.4 OTOF

The DFNB9 locus was mapped to chromosome 2p22–p23 in a large Lebanese family in which congenital profound sensorineural hearing loss followed an autosomal recessive pattern of inheritance. Yasunaga S. *et al.* (1999) showed that the affected individuals in this family were homozygous for a nonsense mutation in the *OTOF* gene. This gene encodes a cytoskeletal protein called otoferlin that may be involved in synaptic vesicle trafficking. Expression of otoferlin in the inner ear was found to be mostly in the inner hair cells. Because of this finding, Varga R. *et al.* (2003) searched for otoferlin mutations in children with recessive forms of AN/AD without peripheral neuropathy. These children had absent ABRs, but their OAEs were preserved, suggesting normal function of their outer hair cells. (For some of these children, OAEs disappeared with time.) In general, they did not benefit from hearing aids and their speech comprehension was poorer than expected based on their pure-tone audiograms, which ranged from moderate to profound. Several of these children received cochlear implants and found them helpful.

3.07.4.1 Structure, Expression, and Function

OTOF consists of 48 exons spanning about 90 kb of genomic DNA. Yasunaga S. *et al.* (2000) detected numerous alternate splice forms involving exons 6, 31, 47, and 48, and several translation initiation sites.

There are two classes of otoferlin isoforms: long ones with approximately 2000 amino acids and six C2-like domains, and short ones (encoded by exons 20–48) with about 1200 amino acids and only the last three C2-like domains. C2 domains bind Ca^{2+} and are often found in proteins involved in signal transduction, vesicle trafficking, and membrane fusion.

Numerous adult human and mouse tissues including the cochlea, vestibule, eye, brain, placenta, liver, heart, lungs, pancreas, skeletal muscle, and kidney, as well as total human fetus, showed *OTOF* expression, with the strongest expression being in the cochlea and brain. The short isoforms were not detected in mouse tissues, whereas the only human tissue in which the long isoforms were detected was the brain. Additionally, the 60 C-terminal amino acids in brain otoferlin are encoded by exon 47, whereas in the cochlea and other tissues, exon 47 is skipped and the 5′ part of exon 48 is used to encode the final 60 amino acids. The strongest expression of *OTOF* in the inner ear of the mouse is in the cochlear inner hair cells and vestibular type I sensory hair cells; it was detected at E19.5 and persisted until at least P20. *OTOF* expression was also detected in the cochlear outer hair cells and spiral ganglion cells of mouse embryos, but it was found only in inner hairs cells of mature cochleas (Yasunaga, S. *et al.*, 1999; 2000).

Otoferlin is related to the *C. elegans* FER-1 protein, as are two other proteins with C2 domains, dysferlin and myoferlin. They are all predicted to be C-terminal membrane-anchored cytosolic proteins, which interact with phospholipids and other proteins via their C2 domains. Otoferlin function is unknown, but the C2-like domains suggest that it may be involved in synaptic vesicle–plasma membrane fusion.

3.07.4.2 Mutations

In the original DFNB9 family, Yasunaga S. *et al.* (1999) showed that the affected individuals were homozygous for a nonsense mutation in exon 39. Of the17 frameshift, splice site, and missense mutations that have been reported so far, five are found in exons that are included only in the long isoforms, which are restricted to the brain. No mutations have been found in exon 47, but three are in exon 48, which is encoded in the cochlea but not in the brain. In the Spanish population, Migliosi V. *et al.* (2002) found that 4.4% of those without *GJB2* mutations have *OTOF* mutations (in particular, Q829X in exon 22), and Rodriguez-Ballesteros M. *et al.* (2003) reported that *OTOF* mutations account for at least 3.5% of prelingual hearing loss.

3.07.4.3 Mouse Models

A mouse model should provide some insight into clarifying the function of otoferlin. However, no spontaneous mutations have yet been reported, and a knockout mouse has not been created.

3.07.5 TECTA

Both dominant (DFNA8/12) and recessive (DFNB21) forms of hearing loss have been associated with mutations in the *TECTA* gene, which encodes α-tectorin, a noncollagenous extracellular matrix protein. The three loci were mapped to chromosome 11q22–q24 in three different families from Austria, Belgium, and Lebanon. *TECTA* was considered a likely candidate gene based on its location (Verhoeven, K. *et al.*, 1998). The dominant phenotype in the Belgian and Austrian families was nonsyndromic, prelingual, stable, moderate-to-severe hearing loss at all frequencies. This is in contrast to most dominant forms of hearing loss, which are progressive and have a postlingual onset. However, affected members of other DFNA8/12 families have the typical progressive loss starting in the high frequencies. The recessive phenotype in the family from Lebanon had a prelingual onset and was in the severe-to-profound range (Mustapha, M. *et al.*, 1999).

3.07.5.1 Structure, Expression, and Function

TECTA has 23 exons encoding a 2155 amino acid protein, α-tectorin. The human DNA sequence is predicted to have 95% identity with the mouse sequence. Splice variants may exist, but have not yet been systematically investigated. The protein has hydrophobic N-terminal signal sequences that are characteristic of secreted proteins. The C-terminal is also hydrophobic and is predicted to have a glycosyl-phosphatidylinositol (GPI) anchor, which is considered to be a signal for directing the protein to the apical surface of the inner ear sensory epithelia. It also has von Willebrand factor (vWF) type D repeats, which are similar to those found in the sperm membrane protein, zonadhesin, and are rich in cysteines, and a C-terminal ZP domain, which is found in proteins in the zona pellucida, the

extracellular matrix that surrounds the unfertilized egg. Zonadhesin is known to bind to the zona pellucida (Legan, P. K. *et al.*, 1997).

TECTA is expressed only in the inner ear, and, in particular, it is found in the tectorial membrane of the cochlea. Developmental studies in the mouse demonstrate that *tecta* mRNA is expressed in the basal cochlear duct by E12.5, throughout the cochlea by E14.5, and reaches its highest level at P3. After that, expression decreases with minimal detectable mRNA at P15 and none at P67 (Maeda, Y. *et al.*, 2001). These results indicate that *TECTA* is expressed at high levels only briefly during the development of the cochlea and suggest that α-tectorin is stable with a long half-life.

Tectorins are pepsin-sensitive glycoproteins that are resistant to digestion with bacterial collagenase. The tectorial membrane is a ribbonlike sheet of extracellular matrix that spirals along the length of the cochlea, and connects to the tips of the stereocilia of the outer hair cells. It is composed of collagens (types II, V, and IX) and a noncollagenous matrix, consisting mostly of α-tectorin and β-tectorin. These two proteins crosslink, and they appear to be critical for attachment of the tectorial membrane to the cochlear epithelium.

3.07.5.2 Mutations

Missense mutations have been found in affected individuals in DFNA8/12 families, and a dominant negative mechanism has been proposed, although haploinsufficiency is also considered possible (Verhoeven, K. *et al.*, 1998). The reasons for the differences in age of onset and phenotypes among affected individuals in DFNA8/12 families is not clear. However, three missense mutations that change cysteine residues at positions 1057, 1619, and 1837 are associated with progressive loss. So far, seven different missense mutations have been reported and to some extent it appears that mutations in the vWF regions cause high-frequency hearing loss, while those in the ZP domain cause mid-frequency loss (Naz, S. *et al.*, 2003).

In the Lebanese DFNB21 family, the affected individuals were homozygous for a splice site mutation. More recently, Naz S. *et al.* (2003) reported exon 5 and exon 20 frameshift mutations in two consanguineous DFNB21 families from Iran and Pakistan. In both families the hearing loss was prelingual and in the moderate-to-severe range.

3.07.5.3 Mouse Models

Homozygous knockout mice have moderate-to-severe hearing loss and abnormal and detached tectorial membranes with no known noncollagenous components. The tectorial membrane is synthesized, but within a few weeks after birth it is no longer attached at either end and the collagen fibers are disorganized. In contrast, the structure and orientation of the stereocilia of the cochlear hair cells are unaffected, although the cochlear microphonic is smaller and differs in phase and symmetry from the wild-type mice. The heterozygous mice appear to be normal (Legan, P. K. *et al.*, 2000). These findings demonstrate the importance of the tectorial membrane in amplifying auditory stimuli, presumably because it is essential for deflection of outer hair cell stereocilia.

3.07.6 Outlook for the Future

Progress in our understanding of genetic hearing loss has been enormous over the past decade. We have made great strides in determining many of the different molecular mechanisms that contribute to the genetic heterogeneity of hearing loss. However, more genes remain to be identified, and elucidating the function of the proteins encoded by these genes is challenging. The four genes discussed in this perspective provide examples of the phenotypic and genetic heterogeneity of hearing loss and the progress that has been made in understanding their function in the inner ear. It is clear that different mutations in the same gene can be associated with both nonsyndromic and syndromic forms of hearing loss, and in some cases a mutation in one copy of the gene (dominant) is sufficient while in others mutations in both copies (recessive) are required for hearing loss. These four genes show diverse expression patterns and the proteins they encode have quite different functions. But they are all critical for normal hearing.

Genetic diagnostic testing for mutations in the *GJB2* gene is becoming routine and other genes are likely to be added in the near future. In particular, testing for the Q829X mutation in the *OTOF* gene might be considered for those who do not have *GJB2* mutations. Ruling out a syndrome is important, especially for one such as Usher syndrome where the first signs of retinal degeneration may not appear for 10 or more years after the diagnosis of severe-to-profound

hearing loss. Because of the genetic heterogeneity of Usher syndrome, a genetic test for all mutations is not yet feasible, but Acadian children should be screened for the *USH1C* 216G→A mutation, and a mutation in the protocadherin 15 gene (R245X) should be considered in those with Ashkenazi Jewish ancestry who do not have mutations in the *GJB2* gene.

A genetic diagnosis is relevant not just to the affected individual but to all family members, some of whom may choose to be tested before making reproductive decisions. In many cases, knowing the genotype is not enough to give a precise phenotype and prognosis, but ongoing research is elucidating some of these relationships. The development of effective therapies based on knowledge of the underlying genetic abnormality is just beginning; however, the potential for molecular intervention strategies as a treatment for hearing loss is promising.

3.08.1 Introduction

Maintaining an appropriate ionic equilibrium between cells and extracellular fluids is essential to cell, organ, and organismal survival. Ion homeostasis is regulated mainly at the cell membrane by a wide variety of transport proteins specialized to selectively move different species of ions into or out of cells. Individual cells have taken advantage of these transport processes to develop their highly specialized functions such as nerve conduction and muscle contractility.

Epithelial cells form tight junctional connections to create barriers specialized to regulate the transcellular movement of ions and molecules between biological compartments. In other cases, groups of cells connected by gap junctions, which allow direct intercellular communication, form a functional syncytium such as in cardiac muscle. Disturbances in ion homeostasis in any of these systems, as occurs in numerous diseases, can lead to organ failure and death.

The inner ear and vestibular system are tiny yet complex organs that regulate the senses of hearing and balance. Both depend on highly organized and interdependent networks of specialized neural, epithelial, and connective tissue cells for normal physiological activity. Alterations in ion transport and fluid homeostasis in one or more of these inner ear cell types underlie the auditory dysfunction seen in metabolic disorders, ischemia, Meniere's disease (Juhn, S. K. *et al.*, 1987; Meyer zum Gottesberge, A. M., 1988; Doi, K. *et al.*, 1992; Salt, A. N. and DeMott, J., 1994; Nadol, J. B. *et al.*, 1995), some forms of presbyacusis (Schulte, B. A. and Schmiedt, R. A., 1992; Schmiedt, R. A., 1993), and in several genetic disorders (see below).

Comprehensive descriptions of structural and functional relationships (Slepecky, N. B., 1996) and homeostatic mechanisms (Wangemann, P. and Schacht, J., 1996; Juhn, S. K. *et al.*, 2001; Wangemann, P., 2002; Trune, D. R., 2006) in the inner ear are available. Much of the past work on hearing and balance disorders has focused on structural and functional changes in sensory HCs, neurons, and the stria vascularis. However, data accumulated over the past decade has established a role for highly specialized populations of fibrocytes in the lateral wall and limbus in maintaining cochlear electrochemical gradients. It is now known that pathological changes in subtypes of cochlear fibrocytes owing to mutation, noise trauma, and aging lead to profound hearing losses. This brief perspective will focus on the role of cochlear fibrocytes in the process, now referred to as potassium (K^+) recycling, and its importance to normal hearing.

3.08.2 Electrochemical Gradients and Cochlear Function

The high positive direct current (DC) resting potential or endocochlear potential (EP) and large K^+, sodium (Na^+), and calcium (Ca^{2+}) gradients between endolymph and perilymph are essential to normal hearing. The EP originates in the intrastrial space and its generation requires the active transport of K^+ into endolymph energized largely by Na^+, K^+-ATPase activity in strial marginal cells (Salt, A. N. *et al.*, 1987; Offner, F. F. *et al.*, 1987; Salt, A. N. and Thalmann, R., 1988; Takeuchi, S. *et al.*, 2000; Marcus, D. C. *et al.*, 2002; Wangemann, P., 2002). The majority of K^+ transported into endolymph is derived from perilymph rather than blood plasma (see Salt, A. N. and Thalmann, R., 1988). Davis H. (1965) first proposed that the EP and the negative diffusion potential of K^+ across the endolymph–perilymph barrier control acoustic transduction. He also postulated the existence of a standing current that exits the scala media through sensory HCs and flows radially across the scala tympani and back to the stria vascularis via the spiral ligament to form a local circuit. Indirect evidence for such a silent current was provided by subsequent physiological studies (Syka, J. *et al.*, 1981; Salt, A. N. and Konishi, T., 1982) and its existence was firmly established through direct measurements by Zidanic M. and Brownell W. E. (1990).

There is little doubt that K^+ is the primary cation carrying both this silent current (Zidanic, M. and Brownell, W. E., 1990; Dallos, P., 1995) and the much larger acoustically evoked transduction currents in auditory HCs (Corey, D. P. and Hudspeth, A. J., 1979; Ohmori, H., 1985; Kros, C. J., 1996). K^+ entering apical transduction channels is effluxed basolaterally through voltage- or Ca^{2+}-gated K^+ channels (Jiang, G. J. *et al.*, 1997; Dulon, D. *et al.*, 1998; Kharkovets, T. *et al.*, 2000; Wangemann, P., 2002). Low extracellular K^+ levels are critical for maintaining steep transmembrane voltage gradients in excitable cells (Giebisch, G. and Wang, W., 1998). Mammalian auditory HCs are bathed in perilymph which has a K^+ concentration ($[K^+]$) of around 3–4 mM. The accumulation of excess K^+ in fluid bathing HCs and neurons would promote depolarization adversely influencing their responses, and could be cytotoxic at too high a level. Thus, there is a need for a mechanism other than simple passive diffusion to maintain low K^+ levels in perilymph surrounding outer HCs as is discussed below.

3.08.3 A Model of Cochlear K^+ Homeostasis

The concept that K^+ leaked or effluxed from endolymph through HCs or supporting cells is actively recycled back to endolymph through a complex series of intercellular and intracellular pathways (Figure 1, Spicer, S. S. and Schulte, B. A., 1998) has rapidly gained acceptance (Steel, K., 1999; Wangemann, P., 2002). Physiological data supporting such a process have existed for years. Investigations showing that K^+ is cleared from the scala tympani to the scala vestibuli much more rapidly than vice versa indicate an active mechanism for K^+ recycling (Salt, A. N. and Ohyama, K., 1993). Evidence is also available documenting the noise-stimulated uptake of K^+ by supporting cells (Oesterle, E. and Dallos, P., 1985; Johnstone, B. M. *et al.*, 1989; Oesterle, E. and Dallos, P., 1990) and electrical connectivity between supporting cells in the organ of Corti (Santos-Sacchi, J. and Dallos, P., 1983; Santos-Sacchi, J., 1991). However, visualizing the nature and extent of the K^+ recycling pathways required new structural and biochemical information. Such data have been provided by studies showing unique morphological and ion transport specializations in inner ear epithelial cells and fibrocytes. At least five different subpopulations of fibrocytes have now been identified in the spiral ligament based on their location, ultrastructural characteristics, and differential expression of ion transport proteins (Schulte, B. A. and Adams, J. C., 1989; Spicer, S. S. and Schulte, B. A., 1991; Schulte, B. A., 1993; McGuirt, J. P. and Schulte, B. A., 1994; Schulte, B. A. and Steel, K. P., 1994; Crouch, J. J. *et al.*, 1997; Hibino, H. *et al.*, 2004). Three of these fibrocyte populations are rich in Na^+, K^+-ATPase and are strategically situated to resorb K^+ from perilymph in the scala tympani (type IV), the scala vestibuli (type V), and the region of the spiral ligament adjacent to the outer sulcus (type II). Each of these cell types is coupled to type I fibrocytes which serve as a final common pathway for moving the resorbed K^+ into the stria vascularis. In addition, electron microscopic studies have demonstrated significant differences in the fine structure of spiral ligament fibrocytes (SLFs) and outer sulcus, Claudius, Hensen, and Deiters cells along the place-frequency map (Spicer, S. S. and Schulte, B. A., 1994a; 1994b; 1996; Spicer, S. S. *et al.*, 2003) supporting their role in ion transport. These data, coupled with a new appreciation for the extent of direct cell-to-cell

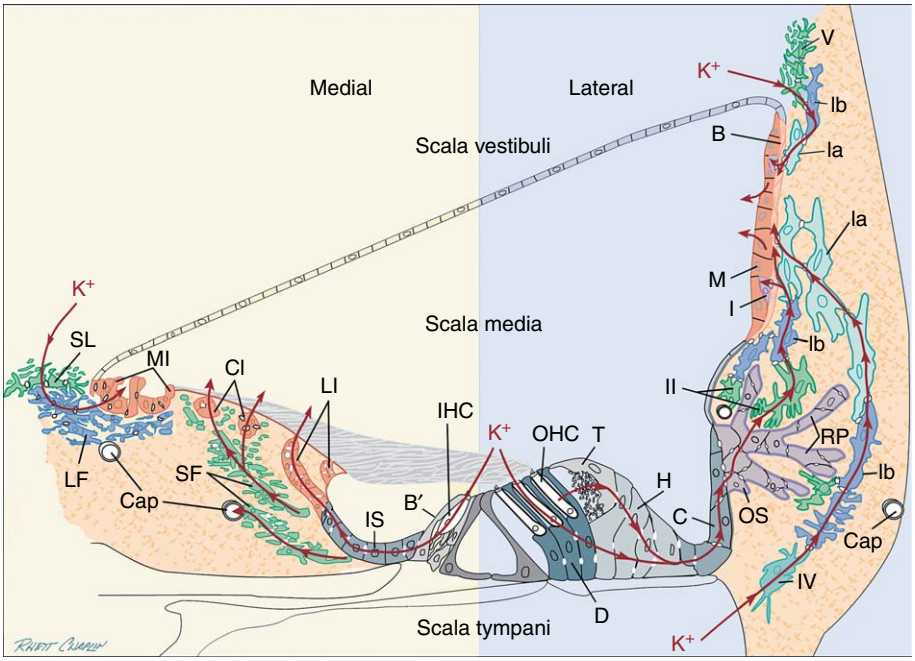

Figure 1 Proposed lateral and medial routes for K^+ homeostasis. In the lateral route, K^+ effluxing from outer hair cells (OHC) is resorbed by Deiters (D) and tectal (T) cells and flows via gap junctions through Hensen (H), Claudius (C), and outer sulcus (OS) cells and their root processes (RP) to efflux into stroma maintained at a low K^+ level by the Na^+,K^+-ATPase activity of type II fibrocytes. Other K^+ ions diffuse into scala tympani and are taken up by type IV fibrocytes. The resorbed K^+ subsequently diffuses via gap junctions through type I fibrocytes (Ia, Ib) and strial basal (B) and intermediate (I) cells into the intrastrial compartment kept low in K^+ by the pumping activity of strial marginal (M) cells. K^+ resorbed by type V fibrocytes from scala vestibuli diffuses downhill through Ib then Ia fibrocytes to the stria. In the medial circuit, ions released from inner hair cells (IHC) diffuse to endolymph through border (B′), inner sulcus (IS) and lateral interdental cells (LI) or pass from IS cells through stellate fibrocytes (SF) to capillaries (Cap) or to central interdental cells (CI) and into the scala media. K^+ pumped from scala vestibuli into supralimbal cells (SL) flows downgradient to light fibrocytes (LF) and medial interdental (MI) cells for return to scala media. Adapted from Spicer, S. S. and Schulte, B. A. 1998. Evidence for a medial K^+ recycling pathway from inner hair cells. Hear. Res., 118, 1–12, with permission from Elsevier.

communication in the inner ear via gap junctions gained by immunostaining for connexins 26, 30, 31, and 43 (Kikuchi, T. *et al.*, 1994; 1995; Lautermann, J. *et al.*, 1999; Kikuchi, T. *et al.*, 2000; Xia, A. P. *et al.*, 2000; Forge, A. *et al.*, 2002) have revealed at least three distinct networks of tightly coupled cells through which K^+ could be recycled (Figure 1). These networks include: (1) the supporting epithelial cells in the organ of Corti; (2) subpopulations of SLFs and basal and intermediate cells in the stria vascularis; and (3) subpopulations of fibrocytes in the spiral limbus.

Correlative electrophysiological and histochemical studies of the developing and aging gerbil inner ear have provided further evidence for the importance of SLFs in establishing and maintaining the EP and cochlear K^+ gradients. The expression of Na^+, K^+-ATPase and the Na–K–Cl cotransporter (NKCC1) in strial marginal cells reaches adult levels well before development of a measurable EP in neonatal gerbils (McGuirt, J. P. *et al.*, 1995; 1996; Sakaguchi, N. *et al.*, 1998). In contrast, expression of the $\alpha 2$ subunit of Na^+, K^+-ATPase and of NKCC1 in SLFs coincides precisely with the onset and rapid growth of the EP, as does the maturation of junctions between strial basal and intermediate cells (Souter, M. and Forge, A., 1998). Loss of Na^+, K^+-ATPase and NKCC1 expression in SLFs also correlates well with strial degeneration and EP declines in the aging cochlea (Schulte, B. A. and Schmiedt, R. A., 1992; Spicer, S. S. *et al.*, 1997; Sakaguchi, N. *et al.*, 1998).

The existence of a medial pathway for recycling K^+ effluxed by inner HCs and afferent nerves back to endolymph has also been postulated (Spicer, S. S. and Schulte, B. A., 1998). This medial route for K^+ homeostasis (Figure 1) is supported by patterns of expression of ion transport mediators in subpopulations of limbal fibrocytes (McGuirt, J. P. and Schulte, B. A., 1994; Schulte, B. A. and Steel, K. P.,

1994; Crouch, J. J. *et al.*, 1997) and similarities in the fine structure of inner phalangeal and Deiters cells, inner sulcus and Claudius cells, and interdental and outer sulcus cells (Spicer, S. S. and Schulte, B. A., 1998). As in the lateral transport system the developmental expression of Na^+, K^+-ATPase (McGuirt, J. P. *et al.*, 1996) and NKCC1 (Sakaguchi, N. *et al.*, 1998) in limbal fibrocytes coincides with the onset of auditory activity in the neonatal gerbil. Further evidence for this medical pathway was provided by the finding that the selective ablation of inner HCs by carboplatin alters cells in the medial flow route and disrupts the tectorial membrane (Spicer, S. S. *et al.*, 1999).

3.08.4 Genetic Evidence in Support of Cochlear K^+ Recycling

A large body of work now points to the importance of gap junctionally coupled syncytial networks to K^+ transport and normal auditory function. Mice lacking the K–Cl cotransporter, normally expressed exclusively in Deiters cells, suffer from deafness and renal tubular acidosis (Boettger, T. *et al.*, 2002). Several studies have revealed a direct link between mutations in connexins 26, 30, 31, and 43 and dominant and recessive forms of human nonsyndromic deafness (Kelsell, D. P. *et al.*, 1997; White, T. W. *et al.*, 1998; Grifa, A. *et al.*, 1999; Liu, X. Z. *et al.*, 2000; 2001). Targeted deletions of either connexin 26 or 30 disrupt the epithelial supporting cell network in the organ of Corti and result in a marked decline in the EP and the endolymphatic $[K^+]$ (Cohen-Salmon, M. *et al.*, 2002; Teubner, B. *et al.*, 2003).

More direct evidence of a role for SLFs in ion transport and normal auditory function derives from studies of mice with spontaneous or targeted mutations in the *Brn*4 gene, a model for DFN3 nonsyndromic deafness (Minowa, O. *et al.*, 1999; Phippard, D. *et al.*, 1999; Xia, A. P. *et al.*, 2002). These mutants have a profound hearing loss, a severely depressed EP, and develop hydrops with the major histopathologic change being chemical and histopathological alterations in SLFs. The sex-linked fidget mutation also results in abolished *Brn*4 gene expression making it an excellent mouse model for the most prevalent form of X-linked congenital deafness in humans (Phippard, D. *et al.*, 2000). Mice lacking a complete gene for pendrin, a model for human Pendred syndrome, fail to express the KCNJ10 protein on strial intermediate cells, lack a positive EP, and show a greatly reduced volume density of type I and II SLFs (Wangemann, P. *et al.*, 2004). Moreover, mice with a deletion of the *Otos* gene, encoding the protein otospiralin, which is normally produced by cochlear and vestibular fibrocytes, exhibit moderate deafness associated with degeneration of type II and IV fibrocytes as the primary pathology. It has been suggested that this dysfunction may predispose these mice to age-related hearing loss (Delprat, B. *et al.*, 2005).

Recent studies of age-related hearing loss further indicate the importance of SLFs to normal auditory function. Hequembourg S. and Liberman M. C. (2001) showed that degeneration of SLFs, in particular of type IV fibrocytes, is a primary cause of the age-related hearing loss, and ultimately sensory cell degeneration, in C57BL/6 mice. This strain carries the *ahl* gene (Johnson, K. R. *et al.*, 2000) as opposed to CBA/CaJ mice which lack this gene and show little age-related hearing loss and no fibrocyte pathology. Wu T. and Marcus D. C. (2003) found that CD-1 mice, which also carry the *ahl* gene, suffer from early onset age-related hearing loss associated with a reduced EP under anoxic conditions, a significant reduction in the endolymphatic $[K^+]$, and pathological changes in SLFs similar to those seen in aging C57BL/6 mice. Interestingly, damage to type II and IV SLFs is also reported to be a major pathology associated with noise-induced hearing loss in CBA/CaJ mice (Wang, Y. *et al.*, 2002).

Human hearing and balance disorders have also been associated with pathological changes in lateral wall fibrocytes which have a distribution and ion transport properties very similar to those found in rodents (Weber, P. C. *et al.*, 2001). An examination of temporal bones from 24 human subjects noted a significant correlation between the loss of type II and IV fibrocytes and age (Kusunoki, T. *et al.*, 2004). Another recent study concluded that the hydrops associated with Meniere's disease is likely the result of compromised cochlear ion homeostasis owing to pathological alterations in SLFs in human temporal bones (Merchant, S. N. *et al.*, 2005). The examination of human inner ears with cochlear otosclerosis, including spiral ligament hyalinization, revealed a loss or decrease of immunostaining for ion transport mediators in type I, II, and IV fibrocytes that was well correlated with degeneration of the stria vascularis and hearing loss (Doherty, J. K. and Linthicum, F. H., 2004). Evidence is thus accumulating that a wide range of inner ear disorders are associated with primary or secondary pathology of ion transport fibrocytes in both animal models and humans.

3.08.5 Fibrocyte Turnover and Replenishment

From a practical standpoint it is perhaps important that, unlike most inner ear cell types, at least some populations of fibrocytes maintain the capacity to divide in the normal and traumatized adult cochlea. Dividing cells have been reported in the spiral ligament and the stroma surrounding nerve fibers in 21-day-old gerbils (Roberson, D. W. and Rubel, E. W., 1994) and cell division has been documented in the spiral ligament of 4–5-week-old mice (Yamashita, H. *et al.*, 1999). Several cell types including fibrocytes in the spiral ligament, limbus, and the sacculus continue to divide in the mature gerbil cochlea, although there is a marked reduction in fibrocyte turnover in aged gerbils (Lang, H. *et al.*, 2003). The chronic administration of furosemide promoted a significant increase in the proliferation of SLFs which was associated with a marked recovery of EP values in 6-month-old gerbils (Lang, H. *et al.*, 2003). Increases in the number of (^{3}H)-thymidine labeled or 5-bromo-2-deoxyuridine (BrdU)-labeled nuclei have also been reported in the spiral ligament of gerbils and mice after acoustic trauma or streptomycin-induced injuries (Roberson, D. W. and Rubel, E. W., 1994; Yamashita, H. *et al.*, 1999). A recent study reported significant increases in the number of BrdU-positive cells in the spiral ligament and acoustic nerve of adult rats and guinea-pigs deafened with kanamycin and ethacrynic acid (Yamasoba, T. *et al.*, 2003). It is interesting to note that no labeling (cell division) was reported in the organ of Corti in the normal or injured ear in any of these investigations on adult animals.

The above data clearly demonstrate that fibrocytes in the spiral ligament and spiral limbus undergo continuous replacement in the adult cochlea and have the capacity to dramatically increase their proliferative index in response to chemical- or noise-induced injuries. This suggests the presence of a population of adult stem/progenitor cells capable of self renewal, although such cells have not yet been identified in the adult mammalian cochlea. It is generally accepted that fibrocytes, along with all other connective tissue elements in the inner ear including cartilage and bone, develop from periotic mesenchyme of mesodermal origin (Lang, H. and Fekete, D. M., 2001; Steel, K. P. *et al.*, 2002). The engraftment of cells derived from clonal expansion of single hematopoietic stem cells in regions corresponding to the location of fibrocytes and mesenchymal cells in the irradiated adult mouse inner ear has recently been documented (Lang, H. *et al.*, 2006). This finding suggests the alternative possibility that bone marrow stem/precursor cells continuously seeded to the inner ear throughout life may serve as a source of fibrocyte progenitors. It is also possible that this is not a normal occurrence but rather reflects the ability of stem/progenitor cells to home to the inner ear after injury, possibly induced by the ablative radiation treatment itself. It is also possible that both of these situations occur. In either event, these data raise the intriguing possibility of restoring or reversing disorders in inner ear ion homeostasis associated with injury to fibrocytes via the manipulation of endogenous or the introduction of exogenous stem/progenitor cells.

Glossary

endolymphatic hydrops A swelling of the membrane-bound endolymphatic compartment of the inner ear.

intratympanic therapy Injection of drug through the tympanic membrane into the middle ear cavity, from where it diffuses into the inner ear through the round window membrane.

3.09.1 Introduction

Meniere's disease is a chronic illness that affects approximately 97 000 Americans annually, usually in adulthood, and with symptoms that subsequently wax and wane over time. Patients often experience a period of intense symptoms followed by years of remission, with relapses in later stages of the disease. Since it was first described by Prosper Meniere in 1861, this illness has defied scientific investigation into its etiology and cure.

The disorder is typically characterized by severe episodic vertigo, fluctuating hearing loss, roaring tinnitus, and a feeling of aural pressure. The characteristics are so unique that just the description of the attack by the patient can lead to a correct diagnosis of the condition. Selective tests can be performed to rule out other conditions in the short list of differential diagnoses.

3.09.2 Pathophysiology

Meniere's disease is characterized by the presence of endolymphatic hydrops, an enlargement of the endolymphatic compartment of the inner ear. Endolymphatic hydrops can be seen in histological sections of the temporal bone as a distension of the

membranous structures such as Reissner's membrane. However, the precise interdependence between endolymphatic hydrops and Meniere's disease remains unclear. Careful studies suggest that hydrops is present in the ears of all patients who exhibit Meniere's disease symptoms, but hydrops is also seen in the ears of substantial numbers of asymptomatic patients (Merchant, S. N. *et al.*, 2005). During the early phases of the disease, there are normal numbers of hair cells and neurons in the organ of Corti, but over time, damage occurs to many structures in the ear. In addition to derangements of the membranous labyrinth walls due to the swollen endolymphatic spaces, there are numerous other pathological changes. These include the loss of spiral ganglion cells, damage to the stereocilia of the hair cells, loss of inner and outer hair cells, and the degeneration of type I and type II fibrocytes of the lateral wall. These degenerative changes occur particularly in the apical turns of the cochlea.

There are a number of animal models of endolymphatic hydrops in which the physiological and anatomical changes have been compared to those in Meniere's disease patients. Endolymphatic hydrops can be induced by surgical ablation of the endolymphatic sac (Kimura, R. and Schuknecht, H. E., 1965), by partial ablation of the sac combined with aldosterone treatments (Dunnebier, E. A. *et al.*, 1997), or by treatments with vasopressin (antidiuretic hormone) (Takeda, T. *et al.*, 2000). Symptoms of Meniere's disease have been associated with hormonal changes during the menstrual cycle in females and may be related to elevated plasma vasopressin levels, but no systemic alterations of aldosterone levels are found in patients (Mateijsen, D. J. *et al.*, 2001).

In animals with surgically induced hydrops, similar anatomical changes are found to those in patients, including degeneration of fibrocytes in the lateral wall, loss of spiral ganglion cells, disruption of hair cell stereocilia, and eventual loss of hair cells (Nadol, J. B., Jr. *et al.*, 1995). In addition, physiological measures indicate that the endocochlear potential (the positive voltage in the endolymphatic space) is reduced, even though the major electrolytes of both endolymph and perilymph are unchanged (Sziklai, I. *et al.*, 1992). One chemical component of endolymph that is disturbed in the hydropic cochlea is the endolymph calcium concentration, which becomes elevated as hydrops develops, probably as a secondary consequence of the endocochlear potential decline (Salt, A. N. and DeMott, J., 1994). We can conclude that endolymphatic hydrops is far from the only pathological change occurring in the ear. It remains unknown how these different pathological processes interact and which are primary, secondary or tertiary. Although it is generally assumed that hydrops is the primary factor, and all other pathologies occur secondarily to hydrops, this remains to be proved. There is recent evidence that changes in fibrocytes in the lateral wall may precede the endolymph volume disturbance (Merchant, S. N. *et al.*, 2005). In this case, hydrops may occur as a secondary consequence of changes in ion transport in the lateral wall.

The observation of endolymphatic hydrops in asymptomatic human ears suggests that some types of hydrops may not be pathological and do not result in hearing loss or other inner ear dysfunction. In experimental animals, acute hydrops can be generated in the normal ear by exposure to loud, but not damaging, low-frequency tones (Salt, A. N., 2004). This type of hydrops does not impair function. On the contrary, the sensitivity of the ear is transiently increased after such tone exposures when hydrops is present. These combined observations demonstrate that endolymphatic hydrops may not be the primary cause of hearing loss in Meniere's disease. Alternative processes, such as the reduction of endocochlear potential and elevation of endolymph Ca^{2+}, may play a bigger role in hearing losses associated with chronic hydrops and Meniere's disease. Hearing acuity is known to be highly sensitive to reductions in endocochlear potential (Sewell, W. F., 1984), while increases in endolymph Ca^{2+} cause shrinkage of the tectorial membrane (Freeman, D. M. *et al.*, 2003) and alter transducer channel conductance and adaptation in hair cells (Hudspeth, A. J., 2005). The exact relationships between endolymphatic hydrops and electrochemical changes of the endolymph still remain uncertain.

When local volume regulation processes are disturbed in the cochlea, the mechanical properties of the endolymphatic system membranes result in volume flows toward or away from the saccule, which is the most compliant structure (Wit, H. P. *et al.*, 2000). Comparable to the weak spot on a balloon, the membranous walls of the saccule appear to be highly distensible. The interactions between the endolymphatic sac and the saccule are not well established, but it has been proposed that distension of the part of the saccule near the endolymphatic duct, called the endolymphatic sinus, may regulate endolymph movements into or out of the endolymphatic sac (Salt, A. N. and Rask-Andersen, H., 2004). The

endolymphatic sac appears to be capable of both resorption and secretion of substances, and is considered the likely ultimate locus for endolymph volume regulation (Rask-Andersen, H. *et al.*, 1999). It is also consistent with the observation of bone or detritus blocking the endolymphatic duct or sac in human temporal bones or vascular occlusions of the sac (Friberg, U. and Rask-Andersen, H., 2002), which may interfere with the sac's role in volume regulation. Another consequence of the distension of the saccular membrane in endolymphatic hydrops is the resulting contact the membrane makes with the undersurface of the stapes footplate. This is thought to lead to a positive Hennebert's sign (induction of dizziness or nystagmus when the stapes is displaced by pneumo-otoscopy) in approximately 30% of patients (Nadol, J. B., Jr., 1977).

3.09.3 Epidemiology

3.09.3.1 Sex Distribution

There is a slightly increased female preponderance among Meniere's patients, although there are some exceptions, such as in Sweden, where the incidence is 57% males to 43% females. In Japan in the 1970s, there was an equal male-to-female incidence that has changed over the last 30 years to a female predominance. The underlying reasons for this remain unknown.

3.09.3.2 Age

The patients who develop this condition are often in the prime of their working lives. The average age of onset has been reported to range between 38 and 50 years of age. The disease is rare in children.

3.09.3.3 Bilaterality

This is a very important consideration, since the illness can lead to severe hearing loss in the affected ear and can influence the treatment decision-making process, especially if destructive procedures are being considered. The incidence of bilaterality has been reported to range from as low as 2% to as high as 47%. Most practitioners will inform patients that the incidence is approximately 20–30%, with an increased incidence the longer they are followed. However, this depends on the criteria being used to determine when the second ear is affected. For instance, a second ear may show a hearing loss but no symptoms of dizziness; some physicians would consider this to be bilateral disease. In a recent study of Meniere's disease patients, 23% developed bilateral disease over an average of 7.6 years (House, J. W. *et al.*, 2006).

3.09.3.4 Hereditary Factors

There are some families that have a strong history of Meniere's disease. One recent study demonstrated that a COCH gene mutation was found in three families with Meniere's disease (Oliveira, C. A. and Braga, A. M., 1992), but in another study HLA class I and class II antigens were not found to increase the susceptibility of developing Meniere's disease (Koyama, S. *et al.*, 1993). Given the rapid identification of mutations that lead to derangements of gene products in the ear, it is reasonable to expect that mutations will be identified that have relevance to endolymph volume regulation.

3.09.3.5 Natural History

The presenting symptoms of Meniere's disease are variable. About 40% of the cases present with a sudden hearing loss, and approximately 50% report acute vertigo as their initial symptom. The incidence of these two symptoms occurring simultaneously ranges from 7% to 44%. When hearing loss is the presenting symptom, most of these patients begin to exhibit vertigo within 2 years. However, when vertigo is the initial symptom, fewer of these cases develop into Meniere's disease.

The audiograms of patients with Meniere's disease have a characteristic appearance. They often start with a low-frequency hearing loss averaging 35 dB, with fluctuations over time back to near-normal range. As the illness progresses, one begins to see associated high-frequency losses that result in a tent-like or peaked audiogram centered at 2000 Hz. Further along in the illness, the peak diminishes to a flat audiogram with further losses in the high frequencies and an associated loss in word identification scores.

Over time in humans, the hearing and vestibular losses plateau and the attacks abate. In this stage, hearing is reduced to the 50–60 dB range and the word identification scores are 50–60%. While these patients find the hearing loss disabling, hearing aids are usually not helpful, due to distortion and poor word discrimination. At this point there is still caloric function, but it, too, is reduced, on average by 50%. It is rare that the caloric function is not maintained to

some degree, but if it is lost 100%, the possibility of other retrocochlear pathology, such as an acoustic neuroma or even autoimmune inner ear disease, should be investigated.

Patients sometimes have a recrudescence of their illness after a period of relative calm. This may result in a frightening disorder characterized by a sudden drop attack known as the otolithic crisis of Tumarkin. During these spells, the patient falls to the ground, without losing consciousness or experiencing a change in hearing. If this occurs, the illness has moved to a dangerous phase, because these sudden drop attacks can cause serious injury. The patient should be treated aggressively at this point.

3.09.4 Evaluation

One of the essential issues in coming to a proper diagnosis of this disorder is to rely on the patient's history. If the patient presents with the classic symptoms of complex episodic vertigo, fluctuating hearing loss, roaring tinnitus, and aural pressure, the diagnosis is only a matter of confirmation and making sure no other condition that can mimic Meniere's disease exists. A thorough otoneurological examination is required and appropriate tests are ordered so that the possibility of retrocochlear pathology can be eliminated.

Electrocochleography can be performed, either with a noninvasive canal wick electrode or with a transtympanic electrode. The latter gives more accurate results, but may cause some injury to the tympanic membrane and, very rarely, to the inner ear. The value of the EcoG is controversial, because if a patient is asymptomatic, results may be normal. Its value for confirming the diagnosis, however, is only when it is positive, not negative. A form of stacked ABR, known as the CHAMP test, has recently been reported to be diagnostic of Meniere's disease although this has not yet been confirmed by other reports (Don, M. *et al.*, 2005).

Click-evoked otoacoustic emissions and $2f_1 - f_2$ distortion product otoacoustic emissions (DPOAE) are both suppressed in the ears of Meniere's patients, but the changes are related to the degree of hearing loss present, and are comparable to other types of hearing loss of similar magnitude. Conventional acoustic emissions are therefore of little additional value over conventional audiometry in the diagnosis of Meniere's disease. Although recent experimental results and theoretical models have shown that even-order distortions ($2f$, $f_2 - f_1$, $f_2 + f_1$) are much more sensitive to endolymph volume disturbances than are the conventional $2f_1 - f_2$ emissions (Sirjani, D. B. *et al.*, 2004), even-order distortions are difficult to record in humans.

Some patients with Meniere's disease have been found to have an autoimmune basis for their condition. If this is suspected, tests are ordered to look for this possibility, which include FTA-ABS, ANA, ESR, RF, CRP, C1q, and an Otoblot test (anti-68 kDa antibody). The Otoblot test (Otoimmune Diagnostics, Buffalo, NY) is especially important in cases of bilateral Meniere's disease. Studies of the basic immunity of the inner ear have shown that the inner ear is immunoresponsive and is quite capable of responding to an immunological challenge that, in itself, can damage inner ear function (Harris, J. P., 1983; Woolf, N. K. and Harris, J. P., 1986).

3.09.5 Treatment

Unfortunately, the common perception by patients, primary care physicians, and often general otolaryngologists is that there is no effective treatment for this disorder. The patient usually has no choice but to find a way to deal with the attacks until the disease burns itself out, which then coincides with the development of severe hearing and vestibular loss.

In a group of patients with Meniere's disease who performed quality-of-life evaluations between attacks and within days of an acute spell, the results were eye-opening. These patients, most of whom were middle-aged, were found to be severely impaired by their illness: their self-rated quality of well-being (QWB) was worse than that of adults with life-threatening illnesses (i.e., AIDS, cancer, renal and pulmonary disease). On days with acute symptoms, Meniere's patients were much more severely affected, scoring worse than noninstitutionalized Alzheimer's patients and elderly patients with severe obstructive pulmonary disease. Additionally, these patients were clinically depressed on the CES depression scale and were also one standard deviation below the mean for the general population on the SFA-12, a widely used measure of general health (Anderson, J. P. and Harris, J. P., 2001). Taken together, these findings underscore the importance of attempting to treat these patients aggressively, rather than letting the disease run its course.

3.09.5.1 Medical Therapy

The first step in managing patients with Meniere's disease is to explain their illness to them. The patients need to be engaged in their therapy to understand how they can take control of this condition. This often includes a change in lifestyle, reduction of stress, increased exercise, and reduced intake of salt and processed foods.

There are a number of studies that show that diuretics can significantly reduce the number of vertigo spells in Meniere's patients, but the hearing loss may continue (van Deelen, G. W. and Huizing, E. H., 1986).

Additionally, if the evaluation shows any form of autoimmunity or a positive Otoblot, high-dose prednisone (60 mg) will be administered for a 3- to 4-week taper. If a response is seen, the patient will either be given pulses of steroids or be referred to rheumatology for better-tolerated immunosuppressive agents such as Humira, Enbrel, or Rituxin.

3.09.5.2 Middle Ear Pressure Manipulations (the Meniett Device)

Experimental studies found that Meniere's patients responded well to treatment in a hypobaric pressure chamber. This effect was thought to be mediated by the positive pressure in the middle ear causing pressure to be applied to the labyrinth relative to the reduced body pressure. The Meniett is a device that, based on these observations, applies a controlled positive pressure to the middle ear space. Superimposed on the steady pressure are very low-frequency (infrasonic) pressure oscillations. The stimuli are transmitted to the middle ear through a pressure-equalizing tympanostomy tube in the tympanic membrane. The pressure manipulations are thought to influence inner ear pressures in a manner that reduces endolymphatic hydrops. This is supported by studies that have shown that low-frequency pressure pulses delivered to the ear of normal animals appear to drive endolymph from the saccule into the endolymphatic sac. In recent clinical trials, there has been a reduction in vestibular attacks after a period ranging from 6 weeks to 4 months (Odkvist, L. M. *et al.*, 2000; Gates, G. *et al.*, 2004; Thomsen, J. *et al.*, 2005). Patients still experience occasional attacks, but they are less frequent than before treatment. No change occurs in their hearing, tinnitus, or activities of daily living.

It should be noted that some patients who receive the pressure-equalizing tympanostomy tube in their tympanic membranes report that this, alone, is effective in controlling their Meniere's disease symptoms (Montandon, P. *et al.*, 1988). Animal studies also demonstrate that hydrops is less pronounced after surgical ablation of the sac, if the tympanic membrane is also perforated. Possible factors contributing to this effect include an increased oxygenation of the ear, a pH increase of inner ear fluids due to lowering of the middle ear CO_2 level, an attenuation of external low-frequency sounds entering the ear, or an increase in low-frequency displacements of the stapes produced by middle ear muscle contractions, such as those occurring during swallowing.

3.09.5.3 Intratympanic Therapies

3.09.5.3.1 Gentamicin

Vestibular ablation through chemical means has recently had resurgence in popularity. Once used only systemically for bilateral cases, it has now become a well-accepted and effective method to stop vestibular attacks in Meniere's disease (Carey, J., 2004; Chia, S. H. *et al.*, 2004). Low doses of gentamicin are injected into the middle ear, with gradual vestibular ablation occurring. The goal is not to destroy the vestibular end organ completely, but to titrate the dose until vestibular symptoms occur, and then watch for possible recurrence of episodic vertigo. By this low-dose titration method, the risk to hearing is reduced to approximately 6% and the overall effective vertigo control is 92%. Repeated doses can be administered as needed for new symptoms.

The only drawback to this method is the temporary instability patients develop as a consequence of vestibular injury incurred by the gentamicin.

3.09.5.3.2 Steroids

Recently, there has been a trend toward intratympanic (IT) injections of corticosteroids to control the symptoms of patients with steroid-responsive Meniere's disease (Barrs, D. M., 2004; Garduno-Anaya, M. A. *et al.*, 2005). This may permit a higher dose of drug to reach the ear than can be given by systemic therapy (Parnes, L. S. *et al.*, 1999), and carries less risk of hearing loss than does IT gentamicin therapy. The mechanism of action of direct application of steroids to the inner ear remains uncertain, and may be mediated indirectly through the immune system, or directly on fluid homeostasis mediated by

glucocorticoid receptors that are present on a variety of cell types in the inner ear, predominantly on the fibrocytes of the lateral wall of the cochlea.

3.09.5.4 Endolymphatic Sac Surgery

Patients who fail medical management may be considered for surgical therapy, although specialists dealing with this disorder differ markedly in their specific opinions. Many otologists recommend endolymphatic sac shunt surgery or endolymphatic sac decompression. This outpatient procedure involves a mastoidectomy to expose the endolymphatic sac; the site is then opened and a silastic drain is placed between the lumen of the sac and the mastoid. Alternatively, the sac is exposed without placing a shunt, a procedure known as decompression. These procedures have few risks to hearing or to other structures, and usually produce a reduction in vertigo in 65–80% of patients (Glasscock, M. E. *et al.*, 1984a; Ress, B. D. and Harris, J. P., 1999). Sac procedures do not statistically improve hearing or prevent tinnitus, but they have been reported to help people reach a stable point in their disease sooner than being left untreated (Quaranta, A. *et al.*, 1998). In controlled clinical studies, this procedure was found to be no more effective than sham surgery performed on the ears under general anesthesia. However, both groups of patients statistically improved over their baseline status, so the value of this surgery is controversial (Thomsen, J. *et al.*, 1981; Bretlau, P. *et al.*, 1984).

3.09.5.5 Vestibular Nerve Sectioning

Sectioning of the vestibular nerve was once a popular procedure, but it has been employed less over the last decade. In this surgery, the posterior fossa or the middle fossa approach exposes the vestibular nerve for its selective sectioning, sparing both the cochlear nerve and the facial nerve. This procedure has been recommended when symptoms are severe and hearing is still quite serviceable. It involves a craniotomy, and thus has the inherent risks of meningitis, CSF leak, and neurological injury (Glasscock, M. E., *et al.*, 1984b; Kemink, J. L. and Hoff, J. T., 1986; Silverstein, H. *et al.*, 1992).

3.09.5.6 Labyrinthectomy

When hearing is reduced by the illness to unserviceable levels (defined as at least 50 dB SRT or less than 50% word identification score), a labyrinthectomy can be recommended. This procedure is the gold standard for procedures in Meniere's disease treatment, against which other methods must be compared (Hammerschlag, P. E. and Schuknecht, H. F., 1981). In this operation, the five vestibular end organs are systematically removed under direct microscopic control, in an approach usually through the mastoid. After removal of these end organs, the inner ear can no longer generate vestibular attacks; but the residual hearing is destroyed as a consequence of the procedure. Patients will be unsteady for several weeks following the surgery, and must undergo central adaptation for the loss of vestibular function through vestibular exercises or physical therapy. This procedure is effective in approximately 95% of cases. One must be certain that there is adequate vestibular function on the contralateral side before the vestibular tissue is removed; otherwise, the patient may end up with a form of Dandy's syndrome where disabling oscillopsia and ataxia are experienced.

Financial disclosure. Dr. Harris holds the patent for the Otoblot test and has a financial interest in Otoimmune Diagnostics, Inc.

3.10.1 Introduction

The auditory periphery of mammals is one of the most remarkable examples of a biomechanical system. It is highly evolved, with tremendous mechanical complexity. What is the reason for such complexity? Why is it not the case for mammals to simply have hair cells tuned to various frequencies attached to their skin to detect motion due to sound? Clearly, the complexity serves the animal by providing greater functionality. This can be appreciated by looking at simpler auditory systems.

One of the simplest hearing organs is that of the fly (*Drosophila melanogaster*), which has tiny feather-like aristas that produce twisting forces in response to sound. This sound receiver mechanically oscillates to activate the Johnston's organ auditory receptors with a moderately damped resonance at about 430 Hz (Gopfert, M. C. and Robert, D., 2001). The sound pressure level (SPL) required to elicit a response, due to wing-generated auditory cues involved in courtship, is in the 70-100 dB range (Eberl, D. F. *et al.*, 1997). An example of a simple anatomy with more complex function than that of the fly is the Müller's organ of the locust. This invertebrate is capable of discriminating sounds at broadly tuned frequencies of approximately 3.5–5, 8, 12, and 19 kHz, corresponding to the four mechanotransduction receptors attached to the tympanic membrane (Michelsen, A., 1966). The best threshold for the receptor cells is about 40 dB SPL. The resonances of the tympanic membrane and attached organs provide the greater number of frequency channels than the fly (Windmill, J. F. *et al.*, 2005). Amphibians evolved to have a basilar papilla with at least a few hundred hair cell receptors in a fluid medium. Other amphibians, birds, and mammals have many thousands of hair cells. Other such examples, where structure that is more complex leads to greater hearing capability, are found in some of the other chapters in this volume.

The peripheral part of the auditory system, comprising the external ear, middle ear, and the inner ear, systematically transforms and transduces environmental sounds into neural impulses in the auditory nerve. The precise biophysical mechanisms relating the input variables to the output variables of some of the subsystems are still being debated. However, there is general agreement that these transformations lead to improved functionality. Five of the most important functional considerations are described below.

1. *Sensitivity.* The human ear is most sensitive to a range of sounds from the loudest at about 120 dB SPL to the softest at about −3 dB SPL. At its most sensitive frequency near 4 kHz, the displacement at the tympanic membrane at the threshold of hearing is less than one-tenth of the diameter of a hydrogen atom. At this threshold, the amount of work that is done at the eardrum is 3×10^{-18} J.[1] In comparison, the amount of work done for the perception of light at the retina is 4×10^{-18} J, which is close to the calculated value at the threshold of hearing.[2] This suggests that at its limits, the two sensory modalities have comparable thresholds.
2. *Dynamic range.* The dynamic range of psychophysical hearing in humans is about 120 dB SPL, corresponding to environmental sounds and vocalized sounds. However, the neurons of the auditory nerve have a dynamic range that is typically less than 60 dB SPL. The mechanics of the organ of Corti (OC) must compensate for this dynamic range mismatch problem.
3. *Frequency range.* Hearing in humans covers a frequency range of about 10 octaves, and in some other mammals this range can be as wide as 11.5 octaves (for ferrets). To handle this processing mechanically, the sensory receptors should have physical variations on a similar scale. However, the large range is achieved over an extraordinarily small space in comparison to the wavelengths of sound.
4. *Frequency resolution.* One of the most important functions of the cochlea is its tonotopic organization, which maps different input frequencies to characteristic places within the cochlea. Like a Fourier frequency analyzer, each characteristic place is most sensitive to a narrow band of

frequencies, which by limiting the bandwidth can reduce the input noise for the individual mechanoreceptor hair cells and thus the auditory nerve.

5. *Sound localization.* The physical characteristics of the pinna and head diffract sound in a spatially-dependent manner. The diffraction pattern provides important cues that allow the more central mechanisms to localize, segregate, and stream different sources of sound.

In this chapter, we follow the chain of acoustomechanical transformations of sound from the pinna to the modulation of tension in inner hair cell (IHC) tip links, which is the final mechanical output variable of the cochlea from our vantage point. The tension in the tip links opens ion channels in the stereocilia, which then starts a chain of biochemical events that leads to the firing of the auditory neurons. We term the physiologically-measurable output of each given subsystem a *proximate variable.* A chain of proximate variables can be thought to lead from the outer ear all the way to the tip-link tensions of the hair cells in the cochlea. Input variables, such as SPL, the morphometry of the anatomical structures, and the mechanical properties of those structures, combine with biomechanical processes to produce the values for these proximate variables.

3.10.2 Theories of Sound Transmission in the Ear

Starting with Helmholtz, mathematical models have played a key role in improving our understanding of the underlying biomechanical processes of the auditory periphery. In comparison to using natural languages to describe the observed phenomena, mathematical formulations have advantages and disadvantages. The advantages include providing a methodology by which it is possible to compactly describe correspondences with reality. The disadvantages are that the descriptions may be incomplete or difficult to validate. A mathematical model is also often a statement of a scientific theory that captures the essence of the current body of empirical observations. The power of a specific model is its ability to evolve as more facts become available, and to be able to predict facts not yet observed. Thus the interplay between theory and experiment allows one to test different hypotheses and generate new hypotheses. In this chapter we provide a foundation for physiological measurements in the form of mathematical models. We present below some common principles, applicable to many parts of the auditory periphery, that can help us understand the transformations of the input variables that lead to the ultimate output variable of hair cell tip-link tension. Several general concepts are presented, including how levers are formed, how Newton's laws apply to otobiomechanics, how sound transmission through different materials can be described by transmission line formulations, and how modes of vibration arise in structures of the ear. A combination of these principles is used to understand how the ear improves sensitivity, frequency range, frequency resolution, dynamic range, and sound localization within the constraints of biological materials and anatomic space.

3.10.2.1 Mechanical and Acoustic Levers

One of the simplest transformations of energy is achieved with a simple mechanical lever. There are numerous places in the auditory periphery where levers produce force and velocity transformations through anatomical changes in length and area. These transformations take place in the context of improving sound transmission at the interfaces of different anatomical structures where there is a change in the impedance. An example of a change in impedance is the low impedance of air to the high impedance of the fluid-filled cochlea. Examples of the lever action at work include an increase in sound pressure due to a decrease in area from the concha of the pinna to the ear canal, an increase in pressure due to the decrease in surface area from the tympanic membrane to the stapes footplate, an increase in force due to the lever ratio in the ossicular chain, an increase in velocity from the stapes footplate to the basilar membrane (BM) due to a decrease in surface area, and the transformation of the BM displacement to hair cell stereocillia tip-link tension due to relative shearing motion between the reticular lamina (RL) and tectorial membrane (TM).

3.10.2.2 Newton's Second Law of Motion

A key principle in describing the dynamic transformation of forces to accelerations in mechanical systems is the well-celebrated Newton's second law of motion, written as

$$F = ma, \qquad [1]$$

which states that when a force F acts upon a mass, it results in an acceleration a. Transformed to the frequency domain and extended to include the effects of resistance and stiffness, Newton's second law becomes,

$$F(\omega) = \left[M + \frac{R}{j\omega} + \frac{K}{(j\omega)^2}\right] a(\omega). \quad [2]$$

Here the sinusoidal force $F(w)$, with radian frequency ω, acts upon an object described by the variables in the square brackets. This object has now been generalized to include mass M, resistance R, and stiffness K. An alternative form of eqn [2] in terms of particle velocity $v(\omega)$ is,

$$F(\omega) = \left[j\omega M + R + \frac{K}{j\omega}\right] v(\omega), \quad [3]$$

where the term in the square bracket is the mechanical impedance Z_m. Sound pressure $P(\omega)$, measured with a microphone, is defined as the force per unit area A. Thus, eqn [3] can be rewritten for acoustics as

$$P(\omega) = \left[j\omega M_a + R_a + \frac{K_a}{j\omega}\right] V(\omega). \quad [4]$$

The term in the square bracket is now the acoustic impedance Z_a, which for uniform properties is the mechanical impedance Z_m divided by A^2, and $V(\omega) = v(\omega)A$ is the volume velocity. One thing to keep in mind is that impedance concepts are limited to linear steady-state analyses. Despite this limitation, eqns [3] and [4] play a prominent role in helping us understand the transformations of forces and pressures to velocities and volume velocities throughout the ear. It is clear from these equations that the velocity of any structure is proportional to the applied force, but inversely proportional to the impedance due to its mass (M), damping (R), and stiffness (K). At resonance the velocity reaches a maximum because the impeding effect of the mass is cancelled by the impeding effect of the stiffness. One of the challenges in efficient sound transmission to the hair cell detectors is in minimizing the impeding effects of fluid damping and stiffness and mass of structures.

3.10.2.3 Transmission Lines

Many problems in sound and vibration can be described by the wave equation that results in part from Newton's laws of motion. The one-dimensional (1D) version of the wave equation was formulated by d'Alembert in 1747 for a vibrating string. It did not take Euler very long (1759) to formulate the first derivation of the wave equation for sound transmission in 1D and later in three dimensions (3D). Solutions to the wave equation have stood the test of time, as is evident by their use in areas that include electromagnetic theory, transverse waves in stretched membranes, blood vessels, and electromagnetic transmission lines. Because it was used so extensively in telephone communication and power line transmission problems, the 1D wave equation is also known as the transmission line equation. In these equations the properties of the transmission system are assumed to be constant along the direction of propagation. A special form of the wave equation exists when a property along the propagation direction varies exponentially. As reviewed by Eisner E. (1967), these equations were originally formulated by Lord Rayleigh and are now known as Webster's horn equation.

Subsequent sections will show that the transmission line formulation can be used to describe ear canal acoustics, the coupling between the canal and tympanic membrane, wave propagation in the cochlea, and transverse motion on the BM. The series of transmission lines that are sequentially coupled may improve frequency bandwidth while maintaining sensitivity of the proximate variables.

3.10.2.4 Modes of Vibration

Anatomical structures and membranes have various modes of vibration with peak responses at modal frequencies due to resonance. These modes of vibrations are not very different from modes of vibrations in the strings of violins, guitars, and pianos, where both ends of the strings are fixed. The resonant frequency is directly proportional to the string tension and density, but inversely proportional to its length. More complicated modes of vibration are found in membranes and plates. In the ear, examples where resonances are a characteristic feature include the pinna and ear canal, tympanic membrane, ossicles, BM, OC, and hair cell stereocilia. Despite the presence of structural resonances in many of the proximate variables, the overall sensitivity of hearing varies smoothly with frequency and does not exhibit sudden changes.[3] Understanding this dichotomy has been challenging.

3.10.2.5 The Input and Output Variables

Which input variable at the ear canal entrance is representative of hearing sensitivity? Which output variable characterizes changes in tension of the inner-hair-cell stereocilia? Possible candidates for the input

variable are pressure as measured with a microphone, volume-velocity (acceleration and displacement), power, or transmittance and reflectance. Since these variables are interrelated, it is difficult to truly separate the effects of one variable from another. However, the use of pressure has some advantages.

Dallos P. (1973) showed that there is good agreement between hearing sensitivity measured behaviorally and the eardrum-to-cochlear pressure transfer function, also called the middle-ear pressure gain resulting from ossicular coupling. It appears that the combined properties of the middle ear and its cochlear load are the dominant determinants of the animal's measured behavioral sensitivity. This has been directly measured in cat (Nedzelnitsky, V., 1980), guinea-pig (Dancer, A. and Franke, R., 1979; 1980; Magnan, P. *et al.*, 1997), gerbil (Olson, E. S., 1998), and human (Puria, S. *et al.*, 1997; Aibara, R. *et al.*, 2001; Puria, S., 2003). In agreement with Dallos P. (1973), Puria S. *et al.* (1997) showed that there is good correlation between the human middle-ear-pressure gain and the behavioral threshold. This suggests that an important proximate variable, at least at the base of cochlea, is fluid pressure in the vestibule.[4]

In the OC it is well accepted that tension in the tip links is the ultimate mechanical variable for the mechanoelectric transduction (Corey, D. P. and Hudspeth, A. J., 1983; Howard, J. and Hudspeth, A. J., 1988). This tension opens ion channels and initiates the flow of ions through the stereocilia bundles, resulting in depolarization of the hair cell body, which results in firing of the auditory nerve.

In the sections that follow we generally follow the path taken by sound from the external ear, through the middle ear, into the fluid filled cochlea. We then analyze the mechanisms that cause the BM and the OC to vibrate, which then results in tension modulations of the hair cell stereocilia tip-links.

3.10.3 External Ear

The external ear consists of the highly visible cartilaginous pinna flange, the cavum concha, and the ear canal buried in the skull. It is generally accepted that sound source localization in a free field consists of two processes. The sound source azimuth is determined using interaural time differences or interaural intensity differences, whichever is the dominant, while sound source elevation is based on spectral cues from the pinna.

There is significant variability in both the size and the shape of the external ear amongst mammals, and the resulting pressure transformation from the free field to the tympanic membrane. Examples of anatomical variations include cone-shaped pinnae in cats to almost flat pinnae in ferrets, numerous invaginations and protuberances of the pinna flange and concha, and changes in ear canal cross-sectional area often accompanied by bends in the canal. The ear canal and concha boost the sound field in the middle frequency range. A key role of the pinna is to diffract the sound in a spatially-dependent manner, and thus augment the sound field's spectral cues. The torso also adds to elevation cues, particularly at low elevations and low frequencies, due to a shadowing effect (Algazi, V. R. *et al.*, 2002).

A common measure of the effects of the external ear is the free field pressure P_{ff} to tympanic membrane pressure P_{tm} transfer function, defined as P_{tm}/P_{ff}. When measured as a function of spatial angle, the magnitude of the ratio is often called the head-related transfer function (HRTF) Not surprisingly, the effects of the anatomical structures on the HRTF are likely to be unique for each species, and vary significantly in individuals of a given species.

The transformation of the free-field sound pressure to that measured at the tympanic membrane is determined by diffraction, scattering, and resonances due to the asymmetric structures along the way. The frequency region where different structures become important occurs when the wavelength of sound becomes smaller than the physical dimensions of a feature of the external ear.

3.10.3.1 Concha and Ear-Canal Resonance

Dimensionally, the largest feature of the human ear with some acoustic consequence is the ear canal, which is approximately 25 mm in length, and 7 mm in diameter, with a corresponding quarter-wavelength resonance near 2.5 kHz with an approximate pressure gain of about 10 dB (Békésy, G., 1960; Shaw, E. A. and Teranishi, R., 1968; Shaw, E. A., 1974). Significant developmental changes in the ear canal dimensions and wall properties take place even up to the age of 24 months (Keefe, D. H. *et al.*, 1993).

The next largest feature is the concha, with a typical height of 19 mm, a width of 16 mm, and a depth of about 10 mm. There is significant individual variation in these dimensions with very little correlation between them or with other pinna dimensions (Algazi, V. R. *et al.*, 2001). The depth mode resonance,

in the 4–5 kHz range, results in a pressure gain of about 10 dB. Both the canal and concha-depth resonances are complementary effects and are approximately independent of angle of the free-field sound and produce a pressure gain that starts at about 1.5 kHz reaching a maximum gain of up to 20 dB near 3–4 kHz and then decreasing again. At frequencies above 5 kHz, the width and depth modes of the concha become important and excitation of these modes is dependent on the angle of incident sound (Shaw, E. A. and Teranishi, R., 1968; Teranishi, R. and Shaw, E. A., 1968).

3.10.3.2 Spatial Diffraction by the Pinna

To a first-order approximation, the pinna flange and the surface of the head mechanically behave as rigid bodies to acoustic waves. In humans and in some animals like ferrets the pinna is immobile, while in other animals like mice and cats the pinna is mobile and able to move under muscular control independent of the skull. Many of the mobile pinnae have a horn-like structure, which improves their sound collecting ability. The larger cone may allow an effective interaural time delay that is greater than is possible for the head alone, while the mobility allows for the possibility to modulate the interaural time difference (Shaw, E. A. and Teranishi, R., 1968).

In humans, the pinna is relatively large (64 mm × 29 mm) but it does not seem to be strongly correlated with a resonant mode (Algazi, V. R. *et al.*, 2001). One role for the larger pinna is to increase directivity and thus reduce background noise. There are several unique geometric features of the pinna that contribute to resonant modes at frequencies above 6–7 kHz. These modes are dependent on the angle of the incident sound and are clearly important for determining the HRTFs measured in individual subjects.

The brain continually calibrates and interprets the HRTFs to infer the location of sound, indicating that there is plasticity in the perception of the spectral cues (Hofman, P. M. *et al.*, 1998). This was demonstrated by modifying the pinna of adult human subjects with a prosthesis so as to disrupt the spectral cues, resulting in poor spatial localization in the vertical plane. However, after a relearning period of about 30–45 days the subjects were able to localize accurately again. Furthermore, the subjects did just as well after removal of the prosthesis, suggesting that the new cues did not interfere with the ability to perceive previous cues.

3.10.3.3 Tympanic Membrane and Ear Canal Interface

The delicate tympanic membrane is located deep inside the skull at the end of the ear canal, likely for protection from mechanical damage. At frequencies above approximately 1 kHz the membrane response is very complex, while the cochlea provides a mainly resistive load (Onchi, Y., 1961; Møller, A. R., 1963; Zwislocki, J., 1963; Khanna, S. M. and Tonndorf, J., 1969; Lynch, T. J., 3rd, *et al.*, 1994; Puria, S. and Allen, J. B., 1998). This resistive load is the primary damping factor of the external ear resonances.

3.10.4 Middle Ear

The ear canal is filled with air that is continuous with the free field. In contrast, the cochlea is filled with cerebrospinal and other salty fluids. The mechanical properties of these media are shown in Table 1. What matters for effective wave propagation is the specific impedance, which is the product of the density and wave speed of the medium. Even though the fluid of the cochlea has mechanical properties close to those of saline, the flexibility of the cochlear partition greatly slows the wave speed, which causes a lower specific impedance and an air-to-cochlea specific impedance ratio of about 1/200.[5] Such a large impedance mismatch would normally cause most of the energy entering the ear canal to reflect and not enter the cochlea.

Table 1 Acoustical and mechanical properties of air, saline, and the input window to the cochlea

Medium	*Density* ρ *(kg m^{-3})*	*Speed of sound* c *(m s^{-1})*	*Specific impedance* $z = \rho c$ *(Pa-s m^{-1})*	*Impedance ratio* $\beta = z/z_{cochlea}$
Air	1.29	350	448	1/212 = 0.0047
Saline	1000	1500	1.5×10^6	15.7
Cochlear input	1000	95 (approx)[a]	9.5×10^4	1

[a]Actually the group velocity of the slow wave, discussed below.

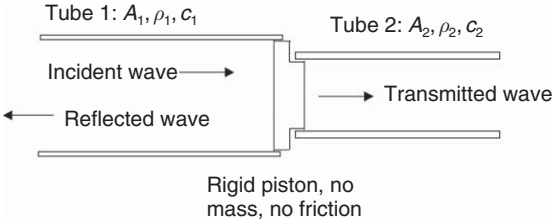

Figure 1 Greatly simplified model for the middle ear consisting of a piston connecting two acoustic tubes. Tube 1 represents the ear canal, containing an incident wave and a wave reflected from the piston. Tube 2 represents the fluid-filled inner ear, containing a transmitted wave.

The above shows that the slower speed of sound in the cochlear fluid reduces the air to fluid specific impedance mismatch by a factor of 15.7 (24 dB). A simple model in Figure 1 illustrates this concept. The model consists of two semi-infinite tubes of cross-sectional areas A_1 and A_2, with the ratio $\alpha = A_1/A_2$, filled with fluids with the densities ρ_1 and ρ_2 and speeds of sound c_1 and c_2. The specific acoustic impedances are $z_1 = \rho_1 c_1$ and $z_2 = \rho_2 c_2$, with the ratio $\beta = z_1/z_2$. The piston has one face in tube 1, and the other face in tube 2.

The hypothetical piston is free from constraint and is massless, so the forces on the two sides of the piston must be equal. An incoming acoustic wave in tube 1 (the ear canal) impinges upon the piston, causing the generation of a transmitted wave in tube 2 (the cochlea), as well as a reverse reflected wave in tube 1. The standard 1D transmission line analysis for acoustic waves yields the ratios of the amplitudes of transmitted and incident pressure (p_2 and $p_{1\text{in}}$ respectively) and energy (E_2 and $E_{1\text{in}}$ respectively),

$$\frac{p_2}{p_{1\text{in}}} = \frac{2\alpha}{1+\alpha\beta}\frac{E_2}{E_{1\text{in}}} = \frac{4\alpha\beta}{(1+\alpha\beta)^2}. \qquad [5]$$

The ratios of the areas of the tympanic membrane and the stapes footplate typical for human and cat give the results in Table 2. For conduction in air, the large ratio greatly improves the energy flowing into the cochlea. Since this is far from 100%, it is not impedance matching, but rather impedance mismatch alleviation. Perfect impedance matching $\alpha\beta = 1$ would provide for humans only a 15 dB improvement in the transmitted pressure, at the considerable cost of a tympanic membrane 10 times larger. It must be noted that larger areas enhance the signal-to-noise ratio at the hair cell level (Nummela, S., 1995).

So the large tympanic membrane is advantageous to humans and cats for hearing in air. It is interesting to consider a change to hearing under water. For this, the air in tube 1 is replaced by water, which yields the results in the bottom section of Table 2. The acoustic pressure transmitted to the cochlea is greatly reduced to a value insensitive to the area ratio. The difference in pressure in air and water of 49 dB is close to the behavioral threshold difference measured in divers (Brandt, J. F. and Hollien, H., 1967; DPA 2005). This supports the simple relation in eqn [5] as a fundamental consideration for the design of the middle ear.

In Table 3 the amplitude of the incident sound wave at threshold is given for hearing in air and water (Fay, R. R., 1988). The pinnipeds (marine mammals including sea lions, walruses, and true seals) spend time in both air and water and have hearing sensitivity worse than humans by a factor of 10 (20 dB) in air and better by a factor of 5 (14 dB) in water. However, the cetaceans (whales and dolphins) have better hearing sensitivity in water than humans by factor of 54 (36 dB) It is interesting that the intensity of the sound at threshold is about the same for humans in air and pinnipeds in water, and for humans in water and pinnipeds in air. Obviously, the middle ear of the pinniped is designed for the water environment. Quite a different middle-ear design provides the extraordinary sensitivity under water of cetaceans (Hemila, S. *et al.*, 1999).

Table 2 Effects of the middle-ear area ratio α and the specific impedance ratio β in transmitting sound pressure and energy into the cochlea, according to the basic model in Figure 1. Replacing the air in the ear canal (tube 1) with saline simulates underwater hearing, which has a great reduction in the transmitted pressure

Tube 1 (EC)	$\beta = z_1/z_2$	$\alpha = A_1/A_2$	p_2/p_1 *(lin)*	p_2/p_1 *(dB)*	E_2/E_1 *(lin)*
Air	0.0047	1	2	6	1.8%
		20 (human)	36	31	25
		40 (cat)	67	36	53
		212	212	46	100
Water	15.7	1	0.12	−18	22
		20 (human)	0.13	−18	1.7
		40 (cat)	0.13	−18	0.6

Table 3 Some approximate thresholds of hearing in air and water

	Air		*Water*	
	Pressure (μPa)	***Intensity ($W m^{-2}$)***	***Pressure (μPa)***	***Intensity ($W m^{-2}$)***
Human	20	8.9×10^{-13}	5400	2.0×10^{-11}
Pinnipeds	200	8.9×10^{-11}	1000	6.7×10^{-13}
Cetaceans	N/A	N/A	100	6.7×10^{-15}

As the simple estimate indicates, without an effective middle ear the sensitivity of the cochlea would be compromised and so would the overall bandwidth, as is evident by pathological conditions of the ear repaired by otologists. As discussed in a subsequent section, another important role of the middle ear is in exerting some degree of dynamic range control at high input levels via the three sets of muscles.

The simple model of Figure 1 is useful to a certain degree, but has significant limitations. In order to build an acoustic lever with an area change from the ear canal to the cochlea requires using biological materials consisting of bone and soft tissues. A rigid piston with a large area requires a large mass, which limits its ability to transduce sound, particularly at the higher frequencies. A membrane is lighter, but has a significant number of resonant modes, particularly at frequencies above 2–3 kHz. In a very thorough study, Nummela S. (1995) showed that malleus and incus masses scale with eardrum area, which further limits high-frequency hearing. These factors must be considered when formulating mathematical models of the middle ear.

More sophisticated models describing sound transmission in the middle ear have been around for some time. Early studies allocated various acoustic influences to the different middle-ear structures interconnected in five to six functional blocks. The blocks were then assigned more detailed elements, which consist of masses, springs, and dashpots. Some of the earliest models by Onchi Y. (1949; 1961), Zwislocki J. (1961), and Møller A. R. (1961) use dynamic analogies and represent the middle ear in the form of electrical circuit models. These phenomenological models have evolved and continue to be useful for understanding surgical interventions of the middle ear (Rosowski, J. J. and Merchant, S. N., 1995; Merchant, S. N. *et al.*, 1997; Rosowski, J. J. *et al.*, 2004). Nevertheless, they have limitations in that there is not a tight relationship between the underlying anatomical structure and function. To overcome these limitations requires models that explicitly incorporate morphometry of the middle ear into their formulation. The first and crucial component is the tympanic membrane, which converts sound pressures in the ear canal into vibrations of the ossicles.

3.10.4.1 Tympanic Membrane Shape and Internal Structure

There remain many unanswered questions regarding the biomechanics of the tympanic membrane. For example, why does the tympanic membrane have a conical shape? Why do the tympanic membrane sublayers have a highly-organized collagen fiber structure? What is the advantage of its angled placement in the ear canal? Why is there symmetrical malleus attachment to the eardrum in some animals while in others there is asymmetry? The functional significance of many of these gross anatomical features of the tympanic membrane is just beginning to be understood and the current status is discussed below.

Helmholtz H. L. F. (1868) discussed the need for impedance matching of the air in the environment and the fluid of the inner ear, and suggested that the tympanic membrane behaved as a piston. This assumption is widely used in lumped parameter (circuit) models of the middle ear, which build upon the free piston model (eqn [5]) by adding springs and the resonances of the malleus–incus complex and of the middle-ear cavity. However, instead of piston-like behavior, surface- displacement measurements on the tympanic membrane have revealed multiple modes of vibration for frequencies above a few kilohertz (Tonndorf, J. and Khanna, S. M., 1972). Since the to-and-fro motion of a resonance mode would reduce the effective area for the sound pressure, the presence of these modes has been difficult to explain. Pioneering work by Rabbitt R. D. and Holmes M. H. (1986) formulated a continuum analytic model with asymptotic approximations for the cat tympanic membrane. They included the membrane geometry and anisotropic ultrastructure in combination with curvilinear membrane equations, but did not analyze the effects of the eardrum angle and the conical shape of the eardrum, and neither have Eiber A. and Freitag H. G. (2002). Current finite-element models

represent the eardrum as an isotropic membrane (Wada, H. *et al.*, 1992; Koike, T. *et al.*, 2002; Gan, R. Z. *et al.*, 2004) and thus do not explain the need for the detailed fiber structure (Lim, D. J., 1995).

Two breakthroughs have increased our understanding of tympanic membrane mechanics. First was the observation that there is significant acoustic delay in eardrum transduction (Olson, E. S., 1998; Puria, S. and Allen, J. B., 1998). Second, the multiple modes of vibration seen on the surface of the eardrum are not transmitted to the cochlea. Rather, the pressure inside the cochlea as a function of frequency remains relatively smooth, even when measured at a high frequency resolution (Magnan, P. *et al.*, 1997; Puria, S. *et al.*, 1997; Olson, E. S., 1998; Aibara, R. *et al.*, 2001; Puria, S., 2003). Clearly these observations are tied to the complicated motions of the eardrum observed by Khanna S. M. and Tonndorf J. (1972), but need further explanation.

3.10.4.2 Tympanic Membrane Biomechanics

To understand the functional consequences of the tympanic membrane structure on its sound transducing capabilities, a biocomputational model has been formulated which leads to some insights on the posed questions (Fay, J. P., 2001; Fay, J. P. *et al.*, 2006). The model incorporates measurements of the geometry of the ear canal (Stinson, M. R. and Khanna, S. M., 1994), the 3D cone shape of the eardrum (Decraemer, W. F. *et al.*, 1991a), and details of the eardrum fiber structure (Lim, D. J., 1995).

The discrete model for the human eardrum is shown in Figure 2, in which a series of adjacent wedges approximate the eardrum. Near the center, the eardrum is attached to the malleus, while the outer edge is attached to the bony annulus (not shown). The 1D acoustic horn equation is used for a small cross-section of the ear canal. The change in area from the adjacent cross-section, the curvature of the centerline, and the flexibility of the portion of the eardrum that intersects with that section of the ear canal are all taken into account. Each strip of the eardrum is curved near the outer edge (locally a toroidal surface) and is straight in the central portion (locally conical) Because the main conical portion contains few circumferential fibers, the approximation is that the radial strips are weakly coupled in the circumferential direction.

The tympanic membrane is represented as a four-layer composite (Figure 2). The input parameters for the formulation are the thickness of each layer as a function of position and the Young's modulus of elasticity (a measure of resistance to deformation) for each layer. The outer-most epidermal layer and the inner-most submucosal layers are relatively flexible. Because the subepidermal and submucosal layers consists of connective tissue and are also relatively flexible, they are included within the epidermal and mucosal layers respectively (Figure 2). The inner two layers contain collagen fibers that are radially-oriented in one layer and circumferentially-oriented in the layer directly below. These two layers, unique to mammals, provide the majority of the scaffolding for the eardrum, and thus those layers mostly determine the stiffness compliance of the membrane. In contrast, the mass comes from the overall thickness of the membrane. Quantitative measurements for cat were used for the overall thickness (Kuypers, L. C. *et al.*, 2005). From these measurements and from sparse measurements of collagen sublayers, the thickness of each sublayer was estimated for human (Figure 2) and cat (Fay, J. P., *et al.*, 2005; 2006).

Direct measurements of the static elasticity of portions of the eardrum (Békésy, G., 1960; Decraemer, W. F. *et al.*, 1980) indicate an effective

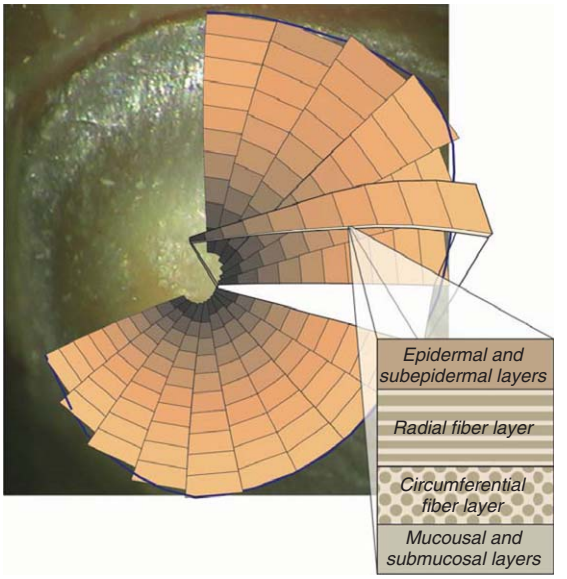

Figure 2 Human eardrum photograph with its biomechanical model representation composed of adjacent wedges. The zoomed box shows the four layer composite of each wedge. The inner radial and circumferential collagen fiber layers, unique to mammals, provide the scaffolding for the tympanic membrane. Dimension and material property differences of the wedges lead to mistuned resonances at high frequencies. The thickness of the eardrum layers increases from the umbo to the tympanic annulus.

modulus of elasticity of around 0.03 GPa. This was re-examined using three very different methods to determine the eardrum modulus of elasticity (Fay, J. P., *et al.*, 2005). First, constitutive models incorporating the Young's modulus of collagen and experimentally-observed fiber densities in cat and human were used. Second, experimental tension and bending measurements (Békésy, G., 1960; Decraemer, W. F. *et al.*, 1980) were reinterpreted using composite laminate theory. And third, dynamic measurements of the cat eardrum surface displacement patterns were combined with a composite shell model. All three methods lead to a similar modulus of elasticity value of 0.1–0.4 GPa for near the center of the eardrum. The corresponding values near the outer edge are approximately half of these values due to the linear taper in the elastic modulus. In previous models the eardrum was treated as a single layer having a uniform elastic modulus, resulting in a low value of elastic modulus (Funnell, W. R. *et al.*, 1987; Prendergast, P. J. *et al.*, 1999; Koike, T. *et al.*, 2002; Gan, R. Z. *et al.*, 2004). In the four-layer model, the collagen fiber sublayers are much thinner than the overall thickness, and hence the estimated elastic modulus is higher.

The modulus of elasticity was combined with the sublayer thickness to formulate a complete model of the cat tympanic membrane. The calculation for the dynamic response of each strip was performed with an algorithm for elastic shells (Steele, C. R. and Shad, K. R., 1995), which places no restriction on wavelength along the strip.

The full 1D interaction of the air in the ear canal and the eardrum is included. Behind the eardrum are the middle-ear cavities and the middle-ear bones connected to the cochlea, for which lumped-element approximations were used. Verification involved mesh refinement studies, comparisons with exact solutions for limiting cases, anatomical values of geometry, best estimate for elasticity, and comparisons with physiological measurements upto 20 kHz, all for the cat middle ear.

Different depths of the eardrum play an important role, as shown in Figure 3. With a shallow eardrum (no cone shape) there is a loss of more than 25 dB for frequencies above about 4 kHz (Figure 3(b), top panel). A deep eardrum shows a response similar to that seen in anatomic specimens, with little loss for low frequencies. Above 4 kHz, the phase for the normal and deep eardrum continues to decrease while for the shallow drum the phase tends to go in the opposite direction and increases. This suggests that there is more phase delay for the deep and normal shape than for shallow eardrums. In comparison to the normal eardrum, the deep drum requires more real estate in the skull, which competes for space with other organs.

The effects of the two collagen-fiber sublayers were also analyzed. This was done by examining the effects of isotropic eardrums that had the same stiffness in the radial and circumferential directions and orthotropic eardrums where there were radial fibers but no circumferential fibers (Fay, J. P., 2001; Fay, J. P. *et al.*, 2006). Results indicate that there is an advantage of the orthotropic microstructure with a dominance of radial fibers in the central region. In the normal drum when both are present, the radial fibers on the inner portion of the tympanic membrane result in an effectively orthotropic membrane while the outer circumferential fibers provide a low-impedance beam-like support. The orthotropic central portion allows maximal sound transmission at both low and high frequencies.

The model calculations indicate that sound transmission from the ear canal to the cochlea varies smoothly despite the fact that there are a significant number of resonances at different points on the eardrum. This suggests a design where drum sections are deliberately mistuned. Because these resonant points are added together at the malleus, no single mode ever dominates. Thus the ensemble of eardrum modes produces a relatively large and yet fairly smooth response at the malleus at the higher frequencies.

Understanding eardrum biomechanics is of critical importance to the development and improvement of myringoplasty, which is a surgical procedure for repairing damaged eardrums. The underlying disease process is often chronic inflammatory disease of the middle ear and mastoid, referred to as chronic otitis media (COM), which leads to a partial or total loss of the tympanic membrane or ossicles. Clinically, isotropic materials like temporalis fascia are used for myringoplasties. To improve hearing results at the higher frequencies, orthotropic material with collagen scaffolding preferentially oriented in the radial direction would be a better choice for improved high-frequency hearing outcomes. Improving postoperative high-frequency results may be important for the perception of sound localization cues present at high frequencies. Currently the standard practice is to measure clinically to 6 kHz. The above results suggest that clinical measurements at frequencies above 6 kHz might better show the effects of different materials.

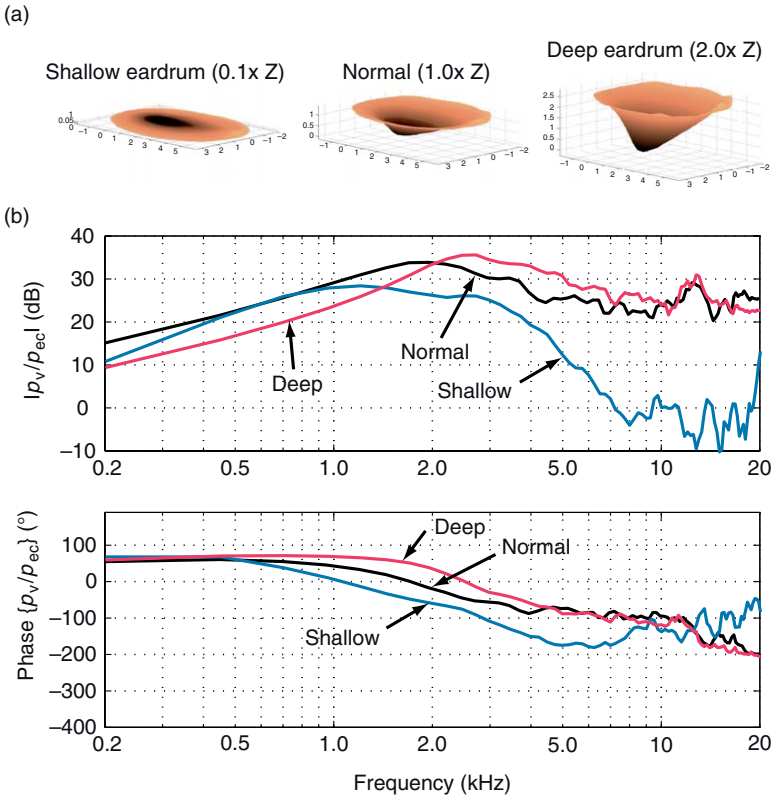

Figure 3 Effects of modifying the eardrum depth. (a) In the center is the anatomically normal eardrum. The *z*-coordinate of all the points is divided by a factor of 10 to obtain the shallow eardrum on the left, and multiplied by a factor of 2 to obtain the steep eardrum on the right. (b) Effects of eardrum depth on the middle-ear pressure transfer function, which is the ratio in decibels of the pressure delivered to the vestibule inside the cochlea (p_v) divided by the input pressure in the ear canal (p_{ec}). The deep eardrum calculation is nearly the same as the normal, but the shallow eardrum has more than a 20 dB loss at higher frequencies. For the normal and deep eardrums, the phase slope is steeper than it is for the shallow drum, indicating more acoustic delay. Reproduced from Fay, J. P., Puria, S., and Steele, C. R. 2006. The discordant eardrum. Proc. Natl. Acad. Sci. U. S. A. 103, 19743–19748, with permission.

Since the modulus of elasticity and the biocomputational approach using asymptotic methods has already been developed for the cat, the challenge will be to estimate eardrum morphometry for other species such as human (Figure 2 shows an approximate guess). Of particular interest is determining how the shape and thickness of the tympanic membrane varies from subject to subject. Such quantification will allow for the possibility of using the eardrum biocomputational model on individual subjects. Nondestructive high-resolution imaging methods are needed to obtain morphometry on individual subjects. A promising new imaging technology is described in the next section.

3.10.4.3 Middle-Ear Imaging

To obtain morphometry of the ear, histological methods have been the primary technique. However, this age-old technique is destructive and certainly not appropriate for *in vivo* imaging of individual subjects. One of the most recent advances for obtaining anatomical information is micro computed tomography (μCT) This has been used to obtain volume reconstructions of the temporal bone of living subjects at a resolution of less than 125 µm (Dalchow, C. V. *et al.*, 2006). *In vitro* resolution can be increased by an order of magnitude (Decraemer, W. F. *et al.*, 2003).

Figure 4 shows an image slice from an intact human cadaver temporal bone ear. The image resolution in the *x*, *y*, and *z* planes is 15 µm (isovolume) Most of the middle-ear structures, including the tympanic membrane cone shape and thickness, ossicles, and suspensory soft tissue, can be visualized because there is good density contrast between these structures and air in the ear canal and middle-ear cavity. Because they provide the best resolution,

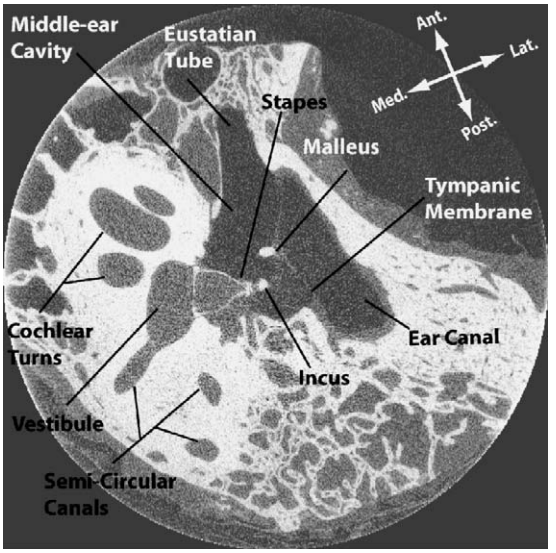

Figure 4 Micro computed tomography (μCT) image of an intact cadaver temporal bone. This is image #769, of 1897 images spanning a length of 28.455 mm. The image illustrates that most of the middle-ear structures can be visualized from an intact temporal bone ear scan. The resolution for both in-plane and out-of-plane (slice thickness) is 15 μm. The tympanic membrane although visible is faint, suggesting that the basic geometry and an approximate thickness can be obtained. The 30.72 mm scan diameter outline is clearly seen.

histological methods remain the standard. However, μCT imaging offers some distinct advantages (Decraemer, W. F. *et al.*, 2003; Puria, S. *et al.*, 2007; Sim, J. H. *et al.*, 2007; Sim and Puria, 2008). These include, (1) elimination of stretching distortions commonly found in histological preparations, (2) use of a nondestructive method, (3) shorter preparation time (hours rather than 12–16 months), and (4) results already in a digital format. This imaging technology is rapidly evolving and it is likely that similar resolutions will be possible for *in vivo* imaging in the near future.

3.10.4.4 Malleus–Incus Complex

The middle ear of most nonmammalian terrestrial animals consists of the tympanic membrane and a columella, while mammals have a tympanic membrane and a malleus–incus complex. Among vertebrates, a great majority of mammals are sensitive to ultrasonic sounds (above 20 kHz), while nonmammals are not.[6] This suggests that the mammalian hearing organ has evolved to be a superior organ for high-frequency hearing compared to those of non-mammals, and that the incorporation of the malleus–incus complex may have something to do with this capability (Fleischer, G., 1978; 1982). However, the biomechanics of this subsystem of the middle ear are not well understood.

Since the time of Helmholtz H. L. F. (1868) the handle of the malleus and the long process of the incus were described as the two arms of a lever with a fixed axis. Ossicle suspension also further supported the notion that the malleus and the incus rotate about a fixed axis while driving the stapes in a piston-like manner. However, detailed measurements of the ossicles have changed this view (Decraemer, W. F. *et al.*, 1991b; Decraemer, W. and Khanna, S., 1995). The malleus motion changes with frequency and all 3D components of translation and rotation are present at biologically relevant stimulation levels. These measurements suggest that a full 3D model of ossicle motion is required.

Between the malleus and incus is a saddle-shaped joint formed from an indentation in the head of the malleus, into which the surface of the body of the incus fits (Figure 5). The incus also has a depression into which a part of the malleus head fits, forming a cog-like mechanism as described by Helmholtz H. L. F. (1868). The significance of such a mechanism is thought to be a locking of the joint causing one part to move with the other during rotation in one direction, but leaving the parts free to rotate in the orthogonal direction (Wever, E. G. and Lawrence, M., 1954). However, measurements (e.g., Helmholtz, H. L. F., 1868; Békésy, G., 1960) have suggested that the incus and malleus are fused together, indicating that there is no slippage at the incudo-malleolar joint (IMJ). Making measurements in the cat ear, Guinan J. J., Jr. and Peake W. T. (1967) showed clear evidence

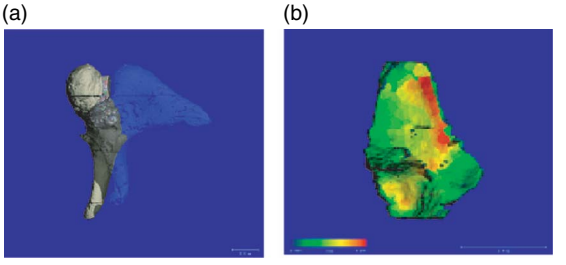

Figure 5 Volume reconstruction of the malleus and incus from μCT slices. (a) The incus is made transparent to allow better visualization of the incudomalleolar joint. (b) The incudomalleolar joint saddle shape and thickness map (0 is dark green while about 300 μm is red).

of slippage at the IMJ above about 8 kHz. Using time-averaged holography measurements Gundersen T. and Høgmoen K. (1976) concluded that the malleus and incus rotate like one stiff body for frequencies below about 2 kHz. Due to these measurements, mathematical models of the human middle ear generally treat the two ossicles as fused, and not allowing slippage (Goode, R. L. *et al.*, 1994; Koike, T. *et al.*, 2002). More recent measurements suggest slippage within the IMJ, and the apparent lack of slippage in previous measurements may have been due to methodological reasons such as the lack of a cochlear load and insensitive measurement techniques (Willi, U. B. *et al.*, 2002). In some animals, like guinea-pig and chinchilla, the IMJ is fused and thus there is no slippage (Puria, S. *et al.*, 2007). In contrast, there is no controversy regarding slippage at the joint between the incus and the stapes, and most mathematical models currently include it (e.g., Goode, R. L. *et al.*, 1994).

Natural mode shape calculations indicate that the ossicles can be treated as rigid bodies only for frequencies below about 3.5 kHz (e.g., Beer, H. J. *et al.*, 1999). Consequently, the ossicles have been modeled as finite elements, which require much more computation time. An alternative approach is to model the ossicles as elastic bodies incorporating just the first two or three modes in each body (Sim, J. H. *et al.*, 2003).

Not unlike the biological ligaments found in other parts of the body, the suspensory ligaments and tendons of the middle ear are a composite, consisting of collagen and elastin embedded in an amorphous intercellular material often called ground substance or matrix which is composed of proteoglycans, plasma constituents, metabolites, water, and ions. Almost two-thirds of the weight of ligaments is due to water, while about three-quarters of the remaining weight can be attributed to the fibrillar protein collagen (reviewed by Weiss, J. and Gardiner, J., 2001). Like the eardrum, the primary component resisting tensile stress in ligaments and tendons is collagen. The primary role of the ground substance is in maintenance of the collagen scaffolding. As such, the biomechanical behavior of a ligament is determined by its geometry, shape of the articulating joint surfaces, orientation and type of insertions to bone, *in situ* pretension, and material properties. What role do the suspensory ligaments play in the complicated 3D vibrations of the middle-ear bones? This question has yet to be addressed with any degree of satisfaction.

In the cat study discussed above, a simple ball and stick model for the malleus–incus complex was used (Fay, J. P. *et al.*, 2006). This was a gross simplification, but allowed concentration on the tympanic membrane biomechanics. A goal of several laboratories is to combine anatomical data with human cadaver temporal bone malleus–incus complex 3D motions into a computational model for individual ears, which should increase understanding of the functional consequences of the anatomy of the ossicles and suspensory ligaments and tendons.

The biomechanical characterization of the malleus–incus complex requires morphological and dynamical measurements from individual ears. The centers of mass, moments of inertia, and anatomical locations and orientations of the ligaments and tensor-tympani tendon are obtained from 3D volume reconstructions (Figure 6) based on μCT images of the isolated preparation.

The morphometry is used to construct a computational biomechanical model for the malleus–incus complex that includes ligament and tendon attachments to the bony walls and muscles, and slippage at the IMJ. Bending of the malleus and incus handles is also allowed. The viscoelastic parameters of each ligament, tensor tympani tendon, and the IMJ cannot be determined from the morphometry and thus 3D motion measurements are required.

As discussed in previous sections, the biomechanics of the tympanic membrane can be fairly complicated. This implies that the input to the malleus–incus complex is also relatively complicated, and thus it is difficult to deduce the dynamics of ossicles and soft tissue attachments with the sound-driven eardrum. To better understand ossicle dynamics an isolated malleus–incus complex preparation was developed where the tympanic membrane and the stapes were dissected. Without an eardrum or a cochlea, the middle-ear bones have to be driven directly. A tiny magnet and a coil around the tympanic annulus were used to drive the malleus–incus complex (Sim, J. H. *et al.*, 2003). The magnet on the tip of the malleus is oriented to drive it in the forward direction. The preparation is placed on a set of goniometers and malleus–incus motion measurements are made at several points at several different angles. The resulting three-dimensional x, y, and z vector components of velocity at each point are used within the biomechanical model to obtain the soft tissue viscoelastic parameters. The 3D volume reconstructions of the magnet and coil, combined with electromagnetic theory, allows

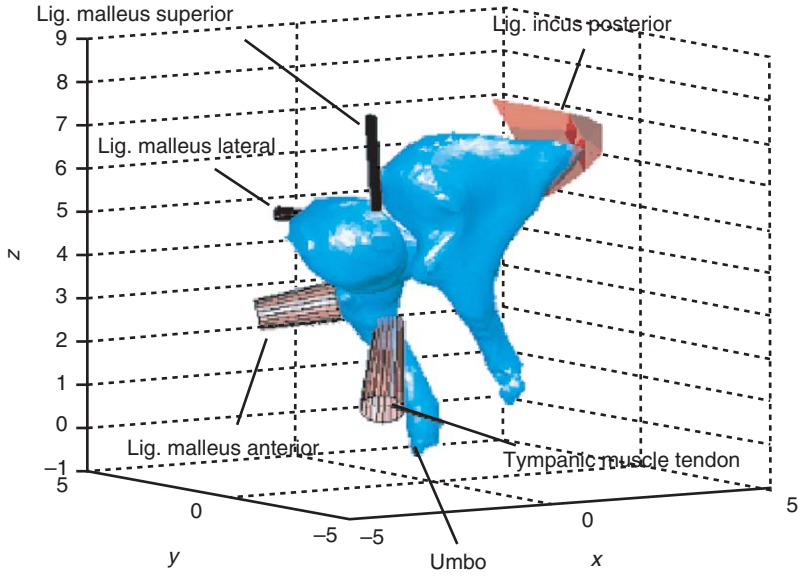

Figure 6 Three-dimensional volume reconstruction of the malleus (left bone), incus (right bone), suspensory ligaments, and the tensor tympani tendon. The soft tissue is represented as tapered cylinders or as a polyhedron. The origin is at the umbo. All dimensions are in millimeters.

accurate calculation of the 3D forces and moments exerted by the magnet onto the malleus. The combined imaging, physiology, and biomechanics approaches should help us better understand the structure and function relationships at audio frequencies in normal and pathological ears.

The above discussion concerns the dynamics of the malleus–incus complex. At high positive and negative static pressures such as during sneezing and coughing, the suspensory ligaments may also play a critical role (Huttenbrink, K. B., 1989). Incorporation of this mode of operation requires extension of the linear models to nonlinear models.

3.10.4.5 Lenticular Process

The inferior end of the long process of the incus terminates in a short perpendicular bend called the lenticular process, consisting of the pedicle and the lenticular plate surrounded by soft tissue. Between the lenticular plate and the stapes head is the incudostapedial joint. Motion from the incus is transmitted to the stapes via this process and thus its mechanical description is of significance.

Most previous modeling work has treated the lenticular process to be a rigid bone that transmits the incus motion directly to the stapes head, or with some slippage due to the incudo-stapedial joint (Beer, H. J. *et al.*, 1999; Koike, T. *et al.*, 2002). Recent anatomical measurements suggest that the platelike bony pedicle is perpendicular to the lenticular plate and is extremely thin and fragile. In cat the dimensions of the pedicle are 240 μm × 160 μm × 55 μm (Funnell, W. R. *et al.*, 2005). Model calculations of static displacements suggest that there is significant relative motion between the incus long process and stapes head (Funnell, W. R. *et al.*, 2005). Funnell W. R. and colleagues have hypothesized that one role for the thin pedicle and lenticular plate arrangement may be to convert the rotational modes of vibration of the incus into translational motion of the stapes. More work is needed to further test this hypothesis.

It has been observed that at high static pressures there is a large lateral displacement of the lenticular process, and that this serves to protect the cochlea from large motions (Huttenbrink, K. B., 1988). Clearly, bending of the pedicle may be involved in such cases.

3.10.4.6 Stapes

The interface between the malleus–incus complex and the vestibule of the fluid-filled cochlea is the stapes, which is held in place in the oval window (Fenestra vestibule) by the annular ligament. The mechanics of the stapes is quite independent of the

malleus–incus complex and of the cochlear fluid load. For this reason the stapes can be considered a semi-independent subsystem of the mammalian ear (Fleischer, G., 1978). This treatment of the stapes is widely accepted (Wada, H. and Kobayashi, T., 1990; Wada, H. *et al.*, 1992; Goode, R. L. *et al.*, 1994; Puria, S. and Allen, J. B., 1998; Beer, H. J. *et al.*, 1999; Koike, T. *et al.*, 2002).

3.10.4.7 Ossicular Reconstruction

While we are discussing the ossicles this is good place to discuss ossiculoplasty, which is the reconstruction of the middle-ear bones to improve hearing sensitivity. Two of the most common pathologies are a missing (or eroded) incus and an ossified stapes. Both result in significant hearing losses. Since the introduction of these surgical procedures more than 50 years ago, ossiculoplasty continues to pose significant challenges to otologists.

The interposition of passive prostheses between the malleus or tympanic membrane and the stapes head or footplate is used to reconstruct the transfer function of the middle ear in the missing or eroded incus condition. These are the incus replacement prostheses. Two types, used depending on the circumstances, are the partial ossicular reconstruction prosthesis (PORP), which is attached to the stapes head, and the total ossicular reconstruction prosthesis (TORP), which is attached to the stapes footplate. The PORP is typically used if there is an intact stapes superstructure. However, ear canal pressure to cochlear pressure transfer function and clinical measurements suggest that even if the stapes superstructure is present, there are acoustico-mechanical advantages to placing the foot of the prosthesis directly onto the footplate (Murugasu, E. *et al.*, 2005; Puria, S. *et al.*, 2005).

In a very different disease process called otosclerosis, the stapes becomes fixed to the surrounding oval window through ossification. The immobile stapes prevents sounds from entering the cochlea and results in significant hearing loss. The precise cause of otosclerosis is not well understood. However, it is becoming well established that otosclerosis is hereditary. Otolaryngologists repair the condition by a procedure called stapedotomy. A hole is made in the footplate, often with a surgical laser (Perkins, R. C., 1980), and then covered with soft tissue to prevent the inner-ear perilymph fluid from leaking out. Sound transmission is then restored with a piston-like prosthesis. One end of the prosthesis is crimped to the long process of the mobile incus, while the other end is inserted into the covered artificial hole in the footplate.

3.10.4.8 Middle-Ear Muscles

The malleus and stapes each have a tendon attached to a tiny muscle, the tensor tympani muscle and the stapedius muscle, respectively. The muscles contract when exposed to high-level sounds, and are part of the middle-ear reflex arc involving the spiral ganglion neurons, the auditory nerve, cochlear nucleus, the superior olive, the facial nerve nucleus, the facial nerve, and the two middle-ear muscles (Margolis, R. H., 1993). This reflex arc can reduce sound transmission through the middle ear at high levels, and may serve to control the dynamic range of the auditory system and to protect the cochlea at high sound levels. The reflex is slow, and thus does not provide protection to the cochlea against sudden impulsive sounds. The time for the stapedius reflex may be on the order of about 20 ms, while the tensor tympani arc is more than ten times slower (Teig, E., 1972).

Two additional functions are attributed to the middle-ear muscle reflex. Low-frequency sounds, particularly when they are high in level, normally tend to mask mid- and high-frequency sounds due to their upward excitation patterns on the BM. One role of the middle-ear muscles is to reduce the level of low-frequency inputs so they do not mask the higher frequency sounds on the BM (Pang, X. D. and Guinan, J. J., Jr., 1997). A second role of the middle-ear reflex is in the reduction of the audibility of self-generated sounds during speech, mastication, yawning, and sneezing (Simmons, F. B. and Beatty, D. L., 1962; Margolis, R. H. and Popelka, G. R., 1975). Because the reflex arc involves so many mechanisms, its measurement is used clinically to diagnose central and peripheral pathologies.

Recently it has been discovered that there are smooth muscle arrays within the peripheral edge of the tympanic membrane, the annulus fibrosus, in all four of the mammalian (bats, rodents, insectivores, and humans) species studied (Henson, O. W., Jr. and Henson, M. M., 2000; Henson, M. M. *et al.*, 2005). The role of this rim of contractile muscle cells in the par tensa region is not clear, but two suggested possibilities are to maintain tension of the tympanic membrane and to control blood flow to the membrane (Henson, M. M. *et al.*, 2005). Measurements indicate that these smooth muscles

can exert control over the input to the cochlea as measured by cochlear microphonics (Yang, X. and Henson, O. W., Jr., 2002).

3.10.4.9 Middle-Ear Cavity

One role of the middle-ear cavity is to act as a baffle for the tympanic membrane so that incident sound does not impinge on both sides of the eardrum. Without this, the sensitivity of the membrane, and thus hearing sensitivity, would be significantly reduced.[7] However, the presence of the cavity results in an increase in overall impedance, due to volume compliance at low frequencies and resonant modes at high frequencies. An increase in middle-ear impedance results in a decrease in hearing sensitivity (Wiener, F. M. *et al.*, 1966).

In humans the middle-ear cavity is relatively large, but is irregular in shape. The mastoid cavity portion has many air cells, or air pockets, that result in an increase in surface area. Each cell is lined by a mucous membrane of thin epithelial cells. It is thought that the irregular shape minimizes resonant modes, and that the air cells effectively dampen remaining resonances (Fleisher, G., 1978).

3.10.4.10 Middle-Ear Acoustic Load

The primary load to the middle ear is the acoustic input impedance of the cochlea Z_c. As defined by Zwislocki J. J. (1975), Z_c is the ratio of sound pressure in the scala vestibuli (SV) at the stapes footplate to the volume velocity of the footplate. Based on simplifications to the equations of motion at the base of the cochlea, Zwislocki J. J. (1948; 1965; 1975) predicted that the cochlear input impedance is primarily resistive. Direct measurements in the cat (Lynch, T. J., 3rd, *et al.*, 1982), guinea-pig (Dancer, A. and Franke, R., 1980), and human cadaver ears (Aibara, R. *et al.*, 2001) suggest that the prediction by Zwislocki was essentially correct for a broad range of frequencies.

Zwislocki's calculation had not included effects from the apical region of the cochlea. Calculations of the cochlear input impedance, using models that include the apical region and treat the cochlea as a box with constant scalae area, show that below approximately 1–2 kHz, the cochlear input impedance magnitude decreases and becomes more mass-like. This calculated result diverges from the measured data and from Zwislocki's prediction (Puria, S. and Allen, J. B., 1991; Shera, C. A. and Zweig, G., 1991). The decrease in the acoustic impedance and mass-like response is shown to be due to the use of a constant cross-sectional area for the scala vestibule and scala tympani (ST) in all standard box models. Using a more realistic scalae area that decreases from the base to the apex of the cochlea avoids the diverging catastrophe in the model calculations of cochlear input impedance at low frequencies.

The resistive nature of the cochlear input impedance, which is the primary damping component of sound transmission in the middle ear, has two consequences. Foremost is that a large fraction of the acoustic energy that enters the cochlea is absorbed by it rather than being reflected by it. Second, is that it smoothes out the peaks and valleys resulting from any resonances in the middle-ear structures.

3.10.5 Cochlear Hydrodynamics

In the preceding section, methods of imaging, physiology, and computational biomechanics were presented in the context of understanding the relationships between the various acousto-mechanical transformations performed by the middle ear. The end result is that the proximate output variable of the middle ear, which is the vestibule pressure at the base of cochlea, smoothly varies with frequency, and typically with pressure gain, for a wide bandwidth relevant to the species. In the following sections we analyze how sound energy at the base of the cochlea propagates within the cochlea. Much effort has been devoted to this topic, on which many survey papers have been written, as represented by Allen J. B. and Neely S. T. (1992), Nobili R. *et al.* (1998), and de Boer E. (1991; 2006), which provide a summary of current thought. Other chapters in this book address different aspects of cochlear function. Our focus is on what appear to be the key acousto-mechanical transformations that have a basis in the physiology.

3.10.5.1 Vestibular Fluid Pressure

A simple description of what happens to the pressure transmitted into the cochlea by the middle ear is shown in Figure 7 for a given frequency. This represents a standard tapered box model of the cochlea with two symmetric fluid ducts divided by a partition. The stapes provides the input pressure. The wall of the cochlea is bone, which is normally assumed to be rigid, so for air-conducted sound the stapes and round window have equal and opposite volume displacements, preserving the volume of

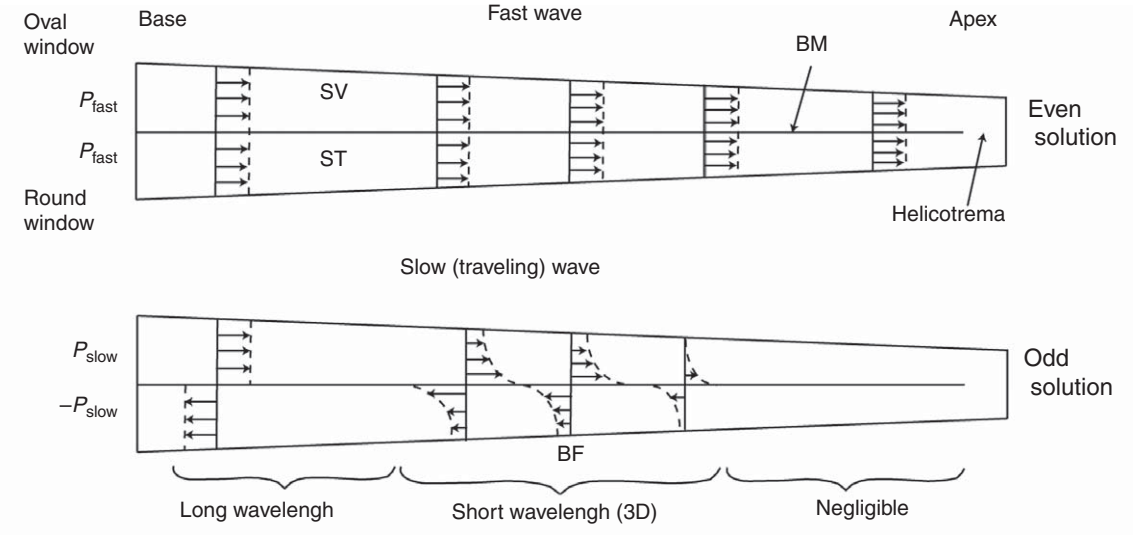

Figure 7 Simple tapered box model for the pressure in the cochlea. The fluid regions scala vestibuli (SV) and scala tympani (ST) with tapered areas are divided by the partition containing the elastic basilar membrane (BM). At the apex the partition has an opening, the helicotrema. The input sound pressure acts at the oval window (stapes) The response for a single frequency is divided into an even (symmetric) solution with equal pressure in SV and ST, and an odd (asymmetric) solution with the pressures in SV and ST of opposite sign. The symmetric solution causes a compression of the fluid, so the wave travels with the speed of sound in saline, which is the fast wave in the upper drawing. In contrast, the asymmetric solution has a net pressure on the partition, which causes a displacement of the BM that slows the wave considerably. This is the slow wave in the lower drawing. Because of the taper of the BM, the stiffness changes and the slow wave has a wavelength that is long near the input but becomes short near the region of maximum amplitude. The driving frequency is the best frequency (BF) for this place. In the region of short wavelength, the fluid motion is three-dimensional (3D), with a pressure that is maximum on the BM and decays exponentially with both the distance from the BM and the distance toward the apex. The round window is compliant, so the total fluid pressure at that location is nearly zero. Thus at the input end, the pressures from the slow and fast waves must cancel in the ST, and so are equal in magnitude.

fluid in the cochlea. However, a very compliant membrane covers the round window, so the fluid pressure at this point is nearly zero. Therefore the total pressure is divided into an even and an odd solution (Peterson, L. C. and Bogert, B. P., 1950), as indicated in Figure 7. The even distribution must cause a compression of the fluid. This corresponds to a wave that travels with the speed of sound in the fluid, which is relatively fast. The odd solution produces net pressure acting on the partition that causes an elastic deformation of the flexible portion of the partition, the BM. This interacts with the fluid motion, causing a wave that is relatively slow. This slow wave is the traveling wave first observed in the guinea-pig by Békésy G. (1952). Because the BM is narrow at the stapes and wide at the apex, there is a gradient in stiffness of the partition, which causes the traveling wave to have a long wavelength near the stapes, then build up to a maximum as the wavelength becomes short. In the very short wavelength region, the viscosity of the fluid causes this wave to die out exponentially. The traveling wave is so slow, relative to the fast wave, that the fast wave can often be approximated as instantaneous, that is, for incompressible fluid.

For simplicity, we consider the properties of the partition to be continuous. The actual tissue consists of discrete elements. As shown by Békésy G. (1960, p. 510) by models with coupled, discrete elements, behavior similar to that of a continuous system can be obtained. This holds, of course, for wavelengths of the response that are long in comparison with the spacing between elements. Many authors use discrete systems directly for advantage in computation and/or construction.

The description in Figure 7 of the spatial pressure distribution for a fixed frequency also holds for the waves seen at a fixed point as frequency varies. For frequencies less than the best frequency (BF), the slow wave has a long wavelength, and for frequencies greater than the BF, the slow wave decays to a negligible magnitude, leaving only the fast wave.

The first direct evidence for this behavior is provided by the measurement of pressure in the gerbil (Olson, E. S., 1998) at a distance 1.2 mm from the stapes. Some of the experimental values are shown in Figure 8,

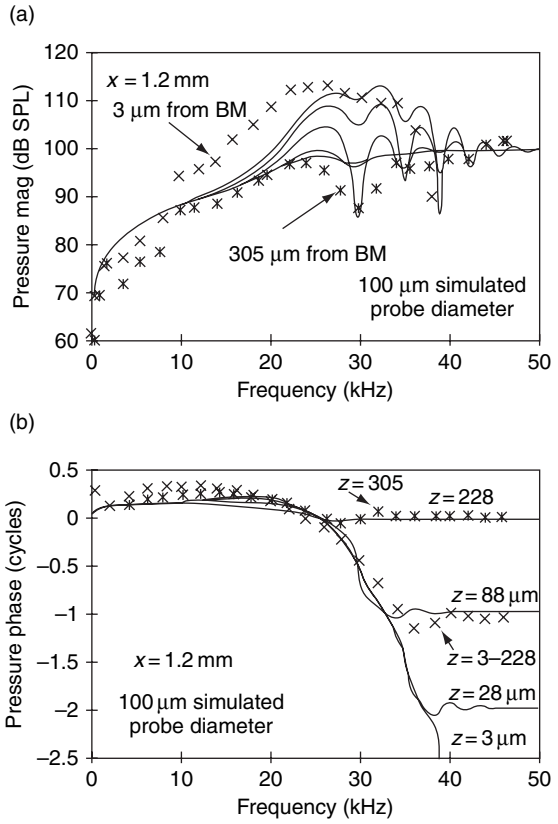

Figure 8 (a) Pressure magnitudes in the scala tympani (ST) region of the gerbil cochlea at a distance of 1.2 mm from the stapes, based on measurements (Olson, E. S., 1998) and calculations (Baker, G. J., 2000). For frequencies higher than best frequency (BF; >40 kHz), the slow wave is negligible and only the fast wave remains (Figure 7). For low frequencies, the fast and slow waves nearly cancel in the ST. Near BF (25 kHz), the fast wave dominates, with three-dimensional (3D) fluid motion that has much higher pressure near the basilar membrane (BM). The 'x' symbols represent measurement points at a distance of 3 μm from the BM, while the '*' symbols represent measurement points at a distance of 305 μm from the BM. Calculated values for some of the intermediate distances between 3 and 305 μm are shown as continuous curves. (b) Pressure phase relative to the simultaneously measured scala vestibule pressure at the base of the cochlea. For frequencies above the BF (>40 kHz), only the fast wave remains. The plateaus differ by one cycle, which shows that the fast wave is uniform with distance from the BM and exactly in phase with the eardrum pressure. For low frequencies, the phases at the different distances from the BM are also the same, corresponding to the fast wave and the long wavelength region of the slow wave. For frequencies approaching the BF (25 kHz), the slow wave dominates and shows the rapid decrease in phase signifying the traveling wave.

along with calculated values from a 3D cochlear model to be discussed later. Near the BF the pressure is strongly dependent on the distance from the BM, with much larger values near the BM (Figure 8(a)). This shows the 3D behavior of the fluid in the short-wavelength region. For low frequencies, the pressures at the different distances from the BM converge, showing the long wavelength region. The phase response shows the near cancellation of the waves for low frequencies (Figure 8(b)). For higher frequencies the slow wave dominates, and the rapid accumulation in phase is characteristic of a traveling wave. For even higher frequencies, the traveling wave disappears, so all that is left is the fast wave with constant phase, which at different distances from the BM differ by one cycle, so these are in fact the same. The phase measurements show that far from the BM (305 μm) the traveling wave quickly disappears, while the points closer (3–228 μm) all have the same phase. In contrast, the calculation shows differences at these points. This may be due to the large pressure probe interfering with the fluid motion, which is only simulated in the calculation by taking the average of the pressure at nine points in the 100 μm diameter of the probe. This is for 80 dB SPL input eardrum pressure. The measured pressure shows a constant value for high frequencies equal to 100 dB SPL. This corresponds to the 80 dB input to the eardrum, with a 26 dB gain through the middle ear, and a 6 dB drop because the fast wave has half the amplitude of the vestibular pressure at the stapes.

3.10.5.2 Partition Resonance

At one time or another almost every component of the cochlea has been suggested as a key tuned resonator that will cause a significant local response for a given frequency (the BF in Figure 7). The BM is the thin compliant portion of the partition that divides the two fluid ducts in Figure 7. The component for which the tuning can be best related to the physical dimensions is the pectinate zone (PZ) of the BM. Mathematical treatments of the BM include both bending stiffness and tension in addition to their interaction with the surrounding fluid. From the mathematical formulation, the frequency range and the place to frequency map of the cochlea can be predicted given the anatomical dimensions and material properties.

3.10.5.2.1 Plate

A cross-section of the BM is sketched in Figure 9. For many mammals, the BM PZ consists of a sandwich of collagen fibers in the radial (y) direction embedded in amorphous ground substance. For the same amount of material thickness, the sandwich provides increased bending stiffness. For simplicity, the details of the sandwich are omitted, and only the motion in the cross-section (y–z plane) is considered. For such a plate, the equation of motion in response to an applied pressure is,

$$D\frac{\partial^4 w}{\partial y^4} - T\frac{\partial^2 w}{\partial y^2} + \rho_P t_P \frac{\partial^2 w}{\partial t^2} = -2p_F, \qquad [6]$$

in which w is the displacement of the plate, T is the tension, ρ_P is the plate density, t_P is the plate thickness, p_F is the pressure in the fluid above the plate, which is doubled in eqn [6] for fluid above and below the plate, and the bending stiffness is $D = f\,Et_P^3/12$, where E is the Young's modulus of the fibers and f is the volume fraction of the fibers. For hinged edges at $y = 0$ and b, the solution is,

$$w = We^{j\omega t}\sin ny \quad n = \pi/b, \qquad [7]$$

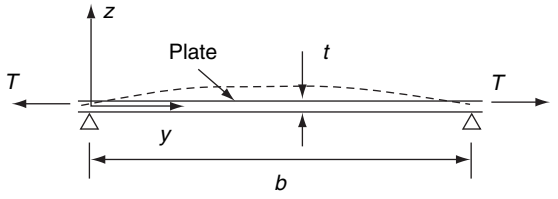

Figure 9 Cross section consisting of an elastic plate in vacuum with tension T. The plate thickness is t and the width between the support points is b. The resonant frequency is proportional to $(T/(tb^2))^{1/2}$. The dashed line shows the deformed position of the plate.

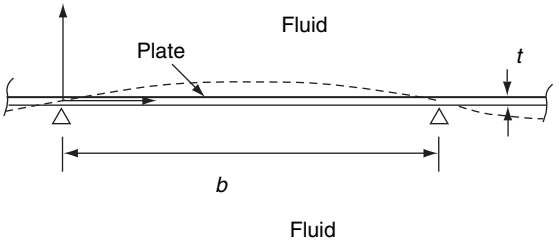

Figure 10 Cross section consisting of an elastic plate in infinite fluid. When the density of plate and fluid are the same, the plate density is negligible, and the resonant frequency is proportional to $(ft^3/b^5)^{1/2}$ where f is the volume fraction of basilar membrane fibers.

in which W is the amplitude and ω is the angular frequency. For static loading and for zero tension, the results for the volume stiffness and point load stiffness are,

$$K_{Vol} = \frac{2p_F}{b\bar{w}} = \frac{\pi}{8}Dn^5, \text{ and} \qquad k_{PtL} = \frac{P}{W} = \frac{48Dd}{b^3}, \qquad [8]$$

where $\bar{w}$ is the average displacement, and P is the magnitude of a load on a probe at the center with diameter d. With all terms retained, eqn [6] yields the impedance as the ratio of the pressure above and below the plate ($2p_F$) and the velocity (v), with $v = \bar{w}$

$$\frac{2p_F}{v} = -\frac{Dn^4 + Tn^2 - t_P\rho_P\omega^2}{j\omega}. \qquad [9]$$

3.10.5.2.2 Fluid

The BM is mainly covered with soft cells that are in contact with extracellular fluid. For the effect of the mass on the pressure distribution, there is little difference between fluid, soft cells, or a gel. As demonstrated by Békésy G. (1960, p. 445) in an experimental model, there is no change in localization when the fluid is replaced by gel. Consequently, for modeling, the soft cells are often replaced by fluid. Both have similar acoustical properties. The motion of an inviscid, incompressible fluid (or gel) is governed by the well-known Laplace's equation,

$$\frac{\partial^2\varphi}{\partial^2 y} + \frac{\partial^2\varphi}{\partial^2 z} = 0, \qquad [10]$$

in which φ is the displacement potential. The z-displacement and pressure are,

$$w = \frac{\partial\varphi}{\partial z}, \text{ and} \qquad p_F = -\rho_F\frac{\partial^2\varphi}{\partial t^2}. \qquad [11]$$

The solution giving the compatible displacement with the plate (eqn [7]) is,

$$\varphi = -\frac{W}{n}e^{j\omega t - nz}\sin ny, \qquad [12]$$

which gives the ratio of pressure to velocity,

$$\frac{p_F}{v} = -\frac{\rho_F\omega}{in} = j\rho_F\omega t_{effective}, \text{ and} \quad t_{effective} = \frac{1}{n} = \frac{b}{\pi}. \qquad [13]$$

Thus the inviscid, incompressible fluid has only the effect of a mass attached to the plate, with an effective thickness $t_{effective}$, over about a third of the plate width b. Soft cells or a gel, representing the OC, also satisfy the same equation, so eqn [13] holds for the fluid consisting of a thin or thick layer of soft cells and fluid. The difference between the fluid with and

without cells attached to the plate lies in the viscous correction, not the effective mass.

3.10.5.2.3 Plate and fluid

Equating the impedance of the plate (eqn [9]) to the impedance of the fluid (eqn [13]) gives the resonant frequency,

$$\omega^2 = \frac{Dn^4 + Tn^2}{\rho_P t_P + 2\rho_F / n}. \qquad [14]$$

Helmholtz H. L. F. (1868) proposed that the transverse fibers of the BM behaved as strings under tension in air, as in a harp. This corresponds to setting the bending stiffness D and the fluid inertia ρ_F to zero in eqn [14]. A sketch of this is in Figure 9 and the result for the first resonant frequency is,

$$\text{frequency}_{\text{Tension}} = \frac{1}{2}\left(\frac{T}{\rho_P t b^2}\right)^{1/2}. \qquad [15]$$

However, there is not much evidence for high tension in the BM and the density of the surrounding fluid is nearly the same as the BM. Consequently, the plate density term ρ_P in eqn [14] is negligible. Setting the tension T and the plate density to zero in eqn [14] gives the resonant frequency,

$$\text{frequency}_{\text{Bending}} = \frac{1}{2\pi}\left(\frac{Dn^5}{2\rho_F}\right)^{1/2} = \frac{1}{2\pi}\left(\frac{E\pi^5}{24\rho_F}\right)^{1/2}\left(\frac{ft^3}{b^5}\right)^{1/2}. \qquad [16]$$

With the BM dimensions and density of fibers (Cabezudo, L. M., 1978), eqn [16] provides a reasonable frequency range for several mammals (Steele, C. R. and Taber, L. A., 1983). The formula also works for recent measurements of the gerbil (Emadi, G. *et al.*, 2004). The wider frequency bandwidth capability for the bending case (eqn [16]) compared to the tension case (eqn [15]) is shown in Table 4. With a nominal Young's modulus of elasticity (E) for collagen, the frequencies computed from eqn [16] are close to the range for the guinea-pig. In contrast, a variation of tension by 10^4 would be required for the tension model to work, which is not justified by the modest change in the dimensions of the BM support. Shown in Table 4 is the width g of the spiral ligament. The tension is assumed to be proportional to g, and the tension frequency is set equal to the bending frequency at the apex for comparison. The conclusion is that it is bending stiffness that determines the frequency localization on the BM (Figure 10).

Table 4 Frequency range capability of the basilar membrane pectinate zone (for guinea-pig) for bending stiffness and tension stiffness

	Base	*Apex*	*Ratio*
Elastic modulus (E)	1 GPa	1 GPa	1
BM fiber vol fract (f)	0.08	0.01	8
BM width (b)	80 μm	180 μm	0.44
BM thickness (t)	7 μm	1 μm	7
Spiral ligament width (g)	200 μm	40 μm	5
Frequency tension	247 Hz	130 Hz	1.9
Frequency bending	52 000 Hz	130 Hz	400

3.10.5.3 Vestibular Fluid Pressure to Basilar Membrane Displacement

The equations for the slow wave (Figure 7), in the model with symmetric SV and ST without Reissner's membrane (e.g., Peterson, L. C. and Bogert, B. P., 1950; Zwislocki, J. J., 1953) can be written as,

$$\frac{\partial}{\partial x}(A\bar{p}) = -\rho_F \frac{\partial^2}{\partial t^2} Q, \text{ and} \qquad [17]$$

$$\frac{\partial}{\partial x} Q = -\Delta A = -\frac{1}{K_{Vol}} 2p_{BM}. \qquad [18]$$

The distance along the BM from the stapes is x, the average pressure in the SV is $\bar{p}$, the pressure acting on the BM is p_{BM}, the volume displacement of fluid in the SV is Q, the area of SV is $A(x)$, and the area displacement of the partition is $\Delta A = b\bar{w}$. Equation [17] follows directly Newton's second law of motion (eqn [1]) while eqn [18] is a statement about conservation of mass in a segment of scala. The equations above are valid for 1D, 2D, and 3D descriptions of the fluid flow by incorporating the dimensionality into the pressure p_{BM} acting on the BM.

3.10.5.3.1 One-dimensional approximation

For long wavelengths, the pressure is nearly constant on the cross section, so the approximation is $p_{BM} = \bar{p}$, and the system is a standard transmission line wave equation. For a single frequency, with all variables changing with $e^{j\omega t}$, this reduces to,

$$\frac{d^2}{dx^2}(A\bar{p}) + m^2(x,\omega)(A\bar{p}) = 0, \qquad [19]$$

where the coefficient m^2 is,

$$m^2(x,\omega) = \frac{2\rho\omega^2}{AK_{Vol}(x)}, \qquad [20]$$

which can be identified as the local wave number. The wavelength is proportional to the reciprocal of the wave number. For the cochlea, K_{Vol} decreases with distance from the stapes, so m increases with distance, meaning that the wavelength becomes short. Because of the simple interpretation, the 1D approximation continues to be the most widely used for cochlear modeling. Zwislocki J. J. (1953) and then later Dallos P. (1973) provide the history of the development. To improve the results, damping and mass are added to the stiffness, as in eqn [2]. However, these values have no physical basis, so this must be considered as a phenomenological model. Another approach is to ignore the physical basis completely and determine the complex wave number $m(x,\omega)$ from measurements of BM displacement phase and amplitude, and the neural response, so that eqn [19] will produce the measured response. This is often used in studies of the function of higher neural centers, for which a simple but reasonable input from the cochlea, described by eqn [19], is desired. Flanagan J. L. and Bird C. M. (1962) developed this approach using Békésy's postmortem measurements of the guinea-pig cochlear response. Of interest is their use of the Hilbert transform to show that the measurements are consistent for a causal and stable system. Zweig G. (1991) further developed the approach for the *in vivo* measurements of Rhode W. S. (1971) in squirrel monkey and obtained self-consistent effective BM impedance. Although the physical behavior is 3D, the traveling wave can indeed be described by an equation in the form of eqn [19]. So the choice is to fit the wave number from the measurements of the response or compute it from the actual stiffness and mass properties of the BM with the 3D fluid motion. Since measurements are difficult and restricted, there is interest in improving and verifying the capability for the direct calculation. de Boer E. (2006) provides a recent perspective on the issues.

3.10.5.3.2 Two-dimensional approximation

To place the cochlear model on a physical basis, more details of the fluid motion must be considered (Ranke, O., 1950; Berkley, D. A. and Lesser, M. B., 1973; Neely, S. T., 1981). When the wavelength is short for large m, the 1D approximation is not valid because the pressure on the BM is much larger than the average pressure, as indicated in the measurements (Figure 8). The 2D approximation (from Laplace's equation in the x–z plane) is,

$$\frac{p_{\mathrm{BM}}}{\bar{p}} = \frac{mH}{\mathrm{Tanh}(mH)} : \begin{cases} 1 & \text{for } mH < 1 \text{ long wavelength} \\ mH & \text{for } mH > 1 \text{ short wavelength} \end{cases}, \quad [21]$$

in which H is the height of the SV. With this, eqn [19] is the same, but the wave number is,

$$m^2 = \frac{2\rho\omega^2}{AK_{\mathrm{Vol}}(x)} \frac{mH}{\tanh(mH)}. \quad [22]$$

For the SV with a square cross-section (such that $A = H^2$) this can be rewritten as,

$$mH\tanh(mH) = \frac{2\rho\omega^2}{K_{\mathrm{Vol}}(x)}, \quad [23]$$

which has the approximation,

$$mH : \begin{cases} \left(\dfrac{2\rho_{\mathrm{F}}\omega^2}{K_{\mathrm{Vol}}(x)}\right)^{1/2} & \text{for } mH < 1 \text{ long wavelength} \\ \dfrac{2\rho_{\mathrm{F}}\omega^2}{K_{\mathrm{Vol}}(x)} & \text{for } mH > 1 \text{ short wavelength} \end{cases}. \quad [24]$$

Thus in the long wavelength region, the wave number is proportional to the frequency, which is the characteristic of nondispersive waves. For the short wavelength region, the wave number is quadratic with the frequency, which indicates dispersion. At the point of partition resonance defined by eqn [16], this has the value,

$$mH \approx \frac{8}{\pi} \quad \text{(partition resonance)}. \quad [25]$$

A dimensionless form of eqn [23] is,

$$\tilde{m} = \frac{8}{\pi} \frac{\bar{\omega}^2}{\tanh\bar{m}}, \quad [26]$$

in which,

$$\tilde{m} = mH, \quad \bar{\omega} = \omega/\omega_{\mathrm{ref}}, \quad \omega_{\mathrm{ref}} = \left(\frac{8}{\pi}\frac{K_{\mathrm{vol}}}{2\rho_{\mathrm{F}}}\right)^{1/2}, \quad \text{and} \quad \tilde{x} = xH.$$

The behavior indicated in the sketch of the slow wave in Figure 7 comes from eqn [23]. Near the stapes, where x is small, the stiffness is large, so the wave number is small, that is, the wavelength is long. As x increases, the wave number increases. The short wavelength region begins when $mH = 1$, after which the wave number increases more rapidly. A little past the beginning of the short wavelength region mH reaches the value shown in eqn [25]. So when the fluid–elastic behavior is considered, eqn [16] is seen

to be a transition point at which the wavelength becomes very short, rather than any local resonance similar to the strings of a harp. When the wavelength becomes rather short, the damping due to the fluid viscosity increases exponentially. It is therefore only a rough approximation to the actual BF. When the fluid viscosity increases, the BF shifts to the base, and when the cross-sectional area A of the scalae decreases, the BF shifts to the apex, with a less rapid decay of the amplitude (Lim, K. M., 2000).

3.10.5.3.3 Three-dimensional model and viscosity

The extension to the 3D analysis of the fluid, including the effects of viscosity, is straightforward but tedious. The pressure at the BM of the 3D fluid is included by making p_{BM} in eqn [21] a function of not just scalae height H, but also the scalae width W. Since the first development (Steele, C. R. and Taber, L. A., 1979), several authors have used various approaches. Advances include the proof that eqn [19] is valid for 3D without any assumption on the form of the solution; only the dispersion relation of eqn [23] is modified (Baker, G. J., 2000; Lim, K. M., 2000; Lim, K. M. and Steele, C. R., 2002). The viscosity of the fluid adds imaginary components to eqn [23], so the wave number m becomes complex. Incorporation of the 3D fluid becomes critical for capturing both the magnitude and phase behavior of the BM response with physical parameters. Several authors (de Boer, E. and Nuttall, A. L., 1999; Kolston, P. J., 2000) offer an alternate inverse approach, in which the 3D equations for the fluid are used to compute the impedance properties of the BM. The results show clearly that there is no significant mass attached to the BM and that near BF the damping becomes negative for low sound pressure, *in vivo*.

3.10.5.3.4 Validation with physical modeling

A comparison of the 1D, 2D, and 3D calculations is shown in Figure 11. For this calculation only the physical properties of fluid and partition measured by Helle R. (1974) are used. The gain in accuracy with 3D is well worth the slight extra effort of calculating the wave number m from the 3D generalization of eqn [23]. For the 1D model to have the correct BF, either the stiffness or mass must be modified from the physical value by a substantial amount.

In recent times, several laboratories have used micromachining to obtain life-sized box models of

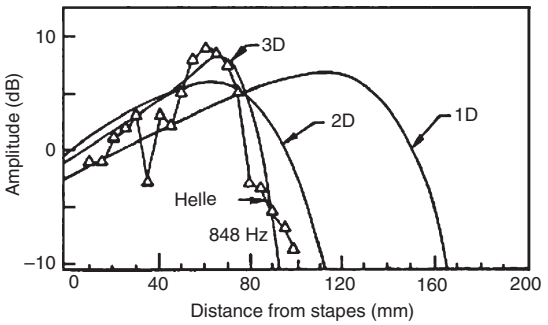

Figure 11 Motion of the basilar membrane (BM) relative to the input for a tone frequency of 848 Hz in an experimental model (Helle, R., 1974). This is a box model of the cochlea, six times human size, with an isotropic polymeric BM. The measured points are shown by Δ symbols. The computations from one-, two-, and three-dimensional approximations (labeled 1D, 2D, and 3D respectively) show that the three-dimensional approximation captures the behavior best (Steele, C. R. and Taber, L. A., 1979). Helle measured all properties, so there are no free parameters.

the cochlea. Traveling waves are found in models with fluid of the viscosity of saline for (1) fluid on one side and the partition stiffness dominated by tension (White, R. D. and Grosh, K., 2005) and (2) fluid on both sides and the stiffness dominated by bending, with 9000 ribs to simulate the orthotropic construction in the real cochlea (Wittbrodt, M. J. *et al.*, 2006). In the latter work, each of four different membrane thicknesses yields reasonable agreement between the calculation from the physical properties and the frequency localization from the 3D WKB calculation discussed in the next section. So finally there is solid evidence that the 3D fluid motion in the cochlea is captured properly by the transmission line eqn [19] with the 3D determination of wave number.

3.10.5.4 Solution Methods

With the advances in computing power, a direct finite difference computation for the full 3D cochlea is appealing. The problem is in the dimensions. With the typical cochlear length 30 times the width, and the BM only one-tenth of the width, and the fluid viscous boundary layer one-tenth of the width of the BM, a fixed mesh requires millions of degrees of freedom. Therefore, even full use of parallel processing (Givelberg, E. and Bunn, J., 2003) requires many hours of computing time, for limited results with a linear model in which the cochlea was coiled and the fluid was viscous. Kiefer J. *et al.* (2006) offer the model

closest to the actual geometry of the human cochlea with the full 3D coiling. However, they use inviscid fluid, which greatly reduces the computing challenge. In comparison, the 1D model eqn [19] can be solved by a variety of numerical methods. Most efficient is an asymptotic method often referred to as WKB. For this, the solution of eqn [19] is written as,

$$A\bar{p} \approx P(x,\omega)e^{j(\omega t-\phi(x,\omega))}, \qquad [27]$$

in which $P(x,\omega)$ is the amplitude function, and the exponential term provides the traveling wave, with the phase given by,

$$\phi(x,\omega) = \int_0^x m(x,\omega)\,\mathrm{d}x. \qquad [28]$$

The viscosity of the fluid contributes a negative imaginary part of the wave number m, which causes the exponential decrease in amplitude of the traveling wave in the short wavelength region. This approach was first used by Ranke O. (1950) on a 2D model for the cochlea. The viscous boundary layer of fluid adds an additional term to eqn [26],

$$\tilde{m} = \frac{8}{\pi}\frac{\tilde{\omega}^2}{\tanh\tilde{m} - \left(1 + j\tilde{\omega}\gamma/\tilde{m}^2\right)^{-1/2}}, \qquad [29]$$

in which the viscosity parameter is,

$$\gamma = \omega_{\mathrm{ref}} H^2 \rho_{\mathrm{F}}/\mu.$$

The viscosity of the fluid is μ. Generally, the term γ is large, so the expansion for the wave number is,

$$\tilde{m} \approx \frac{8\tilde{\omega}^2}{\pi}\left(1 + (1-j)\frac{8\tilde{\omega}^{3/2}}{\pi(2\gamma)^{1/2}} + \cdots\right), \qquad [30]$$

which shows that the fluid viscosity adds to the effective mass with the positive real part of the correction term, and provides the damping with the negative imaginary part. The damping is small for $\tilde{\omega} < 1$ but becomes significant for $\tilde{\omega} > 1$, causing the rapid high-frequency decay in amplitude.

A comparison of the 3D calculations and measurements in the chinchilla is shown in Figure 12. The BM displacement is divided by the stapes displacement, so a linear system would have this response independent of input amplitude. This is not the case for frequencies near the maximum. However, for amplitudes greater than 80 dB SPL, the responses converge, indicating a linear passive behavior, described well by eqn [19] with the 3D extension of eqn [22]. Particularly note the phase in Figure 12(b), which corresponds to eqn [24], linear in frequency for low frequencies and quadratic in frequency for frequencies approaching the BF and higher. This clearly shows the transition of wavelength from long to short near BF. The phase has some dependence on amplitude near BF, but is remarkably insensitive considering the huge change in the amplitude of the input sound.

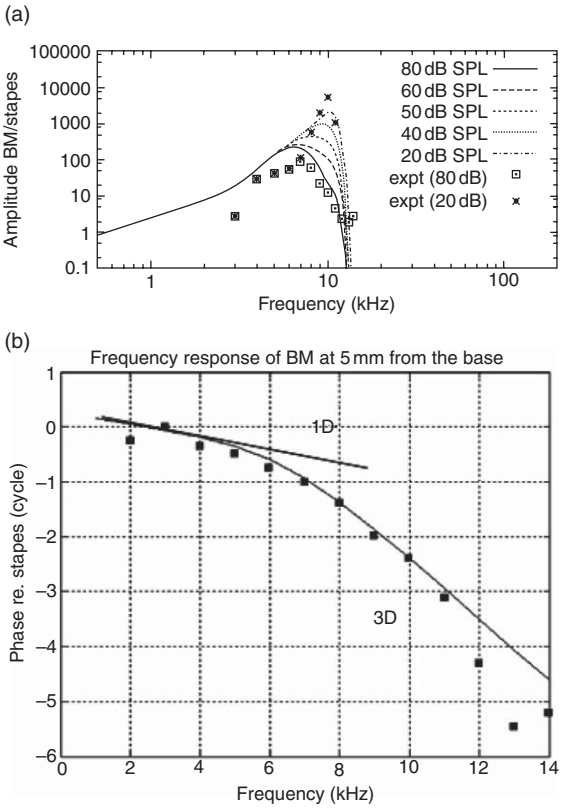

Figure 12 (a) Amplitude of basilar membrane (BM) displacement measured in chinchilla (Ruggero, M. A. *et al.*, 1997) and computed with a three-dimensional (3D) model with saturating feed forward (Lim, K. M. and Steele, C. R., 2002). The amplitude is normalized by the stapes displacement. Experimental points are shown for 20 and 80 dB sound pressure levels (SPL). The active process increases the relative amplitude for low input sound levels. (b) Phase relative to the stapes velocity of BM displacement measured (Ruggero, M. A. *et al.*, 1997) and computed (Lim, K. M. and Steele, C. R., 2002), corrected by Y. J. Yoon. The phase is generally insensitive to amplitude. For low frequencies, the phase is nearly linear with frequency (long wavelength one dimension) Approaching the BF for the given measurement location 5 mm from the base of the cochlea (10 kHz), the phase becomes quadratic, reflecting the dispersive 3D behavior.

A third region that appears in the BM measurements but not in the neural response is the plateau in amplitude and phase just beginning at 13 kHz in Figure 12(a). This has yet to receive an explanation,

but some consider this as evidence for the existence of additional waves. There may well be more than just the fast and slow waves shown in Figure 7.

The form of eqn [27] is also convenient for transients, since the energy for the wave of a given frequency arrives from the stapes at the point x in the time given by,

$$t_{\text{arr}}(x,\omega) = \frac{\partial}{\partial\omega}\phi(x,\omega) = \frac{\partial}{\partial\omega}\int_0^x m(x,\omega)\,\mathrm{d}x. \qquad [31]$$

This approximation can be used to estimate the neural delay (Anderson, D. J. *et al.*, 1971). Thus from Figure 12(b) the low frequencies have a constant low slope of phase, indicating a fast arrival independent of frequency. For higher frequencies, the slope increases in magnitude, indicating an increasingly longer time of arrival at this point and a dispersion of the signal. Note that the slopes depend on the location along the cochlea. We note that the passive cochlea is a causal and stable system. Equation [31] is the group delay of the transfer function relating the response at a point to the input at the stapes.

An important attribute of the auditory system is high-frequency resolution of auditory neurons (Kiang, N. Y. S. *et al.*, 1965). The source of the high resolution, measured as the bandwidth of the response from the peak, is in the BM response (Narayan, S. S. *et al.*, 1998). The sharp frequency discrimination resolution helps reject noise outside the bandwidth of interest for a specific neuron. Thus the sharp resolution is important for increasing the signal-to-noise ratio, particularly at low levels. It is well accepted that the bandwidth of the BM increases as the level increases (Rhode, W. S., 1971, see Figure 12) and this is now believed to be due to nonlinearity in the OC mechanics. Many consider this to be due to the active process that is significant at low levels. For high levels the BM response is linear and described well by the mechanics of the passive box model.

3.10.6 Organ of Corti – Fluid Pressure to Neural Excitation

The inner ear provides the neural excitation for acoustomechanical stimuli. Key to this are receptor cells (hair cells), which transduce mechanical force on cilia (hairs) on one end of the cell into increased firing of neurons via synapses near the other end. The hearing organs provide the sensation for the higher frequencies needed for sound localization and speech reception. Man has an upper frequency for hearing of 20 kHz, while the upper frequency for some bats and toothed whales extends over 150 kHz. As discussed in the previous section, the box model of the cochlea, consisting only of fluid and the BM, results in the localization of the BM displacement and fluid pressure to a certain region for a certain frequency. In the cochlea, the OC is attached to the BM and contains the receptor cells. This is the additional system needed to transform the BM displacements into forces delivered to the cilia. In addition, the OC provides an active input of energy into the traveling wave for low sound levels, which greatly increases the sensitivity and frequency resolution of the BM displacement and neural excitation.

In nonmammalian vertebrates, receptor cells achieve much of their frequency selectivity through the operation of electrical resonance. The ion channels in the basolateral membrane of each cell constitute a miniature electrical circuit that tunes the cell to a specific frequency of mechanical input. However, the mammalian OHC has the unique property of high-frequency electromotility, defined as a change in the cell length in response to a change in the electric potential difference across the cell membrane (Brownell, W. E. *et al.*, 1985). The potential difference across the cell membrane is the result of intracellular voltage depolarization due to ion flow in the stereocilia. Ion channels in the stereocilia are mechanically opened when there is displacement of the bundle in the excitatory direction. The mechanical opening of the ion channels in the inner ear is significantly faster than the cascade of chemical signals required for example in the retina. Therefore, while the sensory receptor hair cells are all mechanoreceptive in the three types of organs in the inner ear, the means for accomplishing their excitation for hearing are much more elaborate. Consequently, the cochlea remains more mysterious than the vestibular system on many levels. As a small example, the most striking geometric feature of coiling of the mammalian cochlea has yet to be adequately explained. Packaging is certainly a consideration. However, West C. D. (1985) finds correlation between hearing and coiling in land animals, while Cai H. *et al.* (2005) compute the low-frequency mechanical effects of coiling and in current work find remarkable correlation of coiling and hearing in sea mammals.

3.10.6.1 Multiscale Organ of Corti Model

The modeling of the OC with the inclusion of more complete anatomical details has received increasing attention in recent years. Kolston P. J. (1999) developed

the first detailed model, in which the components of the OC are simplified to a rectangular grid and the fluid viscosity neglected. He obtained the traveling waves in a significant length of the cochlea. The calculation is by the finite element method (FEM), which is now the prevalent method for structures and for fluid-structure interactions. Cai H. *et al.* (2004) and Andoh M. and Wada H. (2004) use this to consider more realistic geometry for the cross section, but use an approximation for the effect of the longitudinal motion, which is significant for higher frequencies. Another approach is to calculate the stiffness properties of the components of the OC first, and then incorporate the fluid motion in the various compartments of the OC. The components are shown in Figure 13 (Steele, C. R. and Puria, S., 2005).

It is safe to say that the complete solution for the transformation of the BM motion to hair cell excitation for the entire cochlea with a reasonable representation for the OC for all frequencies of excitation has yet to be attained. In the sections that follow, an approach to understanding the complex transduction that takes place in the OC is presented. The model is based on known anatomy and known material properties, with assumptions about how the outer hair cell (OHC) forces may be involved in active amplification using a "feedforward" mechanism. The Amplification and Feedback in Invertebrates chapter summarizes other methods of active amplication that have been proposed.

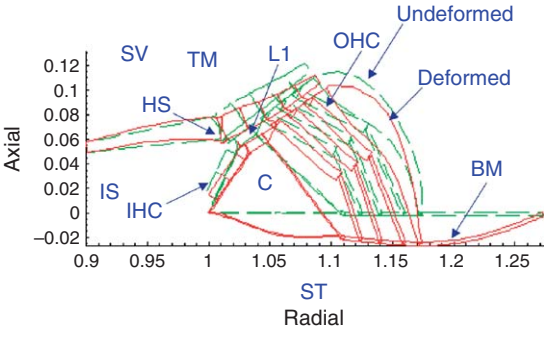

Figure 13 Shell model for guinea pig apex (*y*–*z* plane). The dashed lines show the undeformed configuration, while the solid lines show the deformed configuration due to static pressure loading toward ST, greatly amplified. The radial and axial distances are in mm. The labels are: SV scala vestibule, ST scala tympani, IS inner sulcus, C Cortilymph, TM tectorial membrane, IP inner pillar, OP outer pillar, BM basilar membrane, IHC inner hair cells, OHC outer hair cells, HS Hensen's stripe, and L1 sub-tectorial membrane fluid region.

3.10.6.2 Outer Hair Cell Motility and the Push–Pull Motion of the Basiliar Membrane

Many features of the geometry of the OC have been made clear from detailed measurements in the guinea pig and by a large physical model (Voldrich, L. and Ulehlova, L., 1987). The inclination of the OHC in the radial cross section is evident in Figures 13 and 14. The inclination in the longitudinal direction is shown in Figure 14. The synaptic end of the OHC is supported by Deiters' cell. Each cell has an intracellular axial column consisting of microtubules, referred to as Deiter's rod in Figure 14. One end of the rod cups the end of the OHC and the other end is attached to the BM. The Deiter's rod provides the dominant axial stiffness of the cell. The cup of Deiter's rod at the synaptic end of the OHC also has an attachment to the reticular lamina (RL) with a phalangeal process, shown in Figure 14. The process also consists of microtubules. Thus the triangular arrangement of OHC, RL, and Deiter's process provides a frame of significant elastic stiffness. The OHC is motile (see Chapter Amplification and Feedback in Invertebrates), so a shear of the cilia in the direction to cause hyperpolarization of the cell causes an expansion of the cell, which causes a push down on the BM through the rod. The interesting

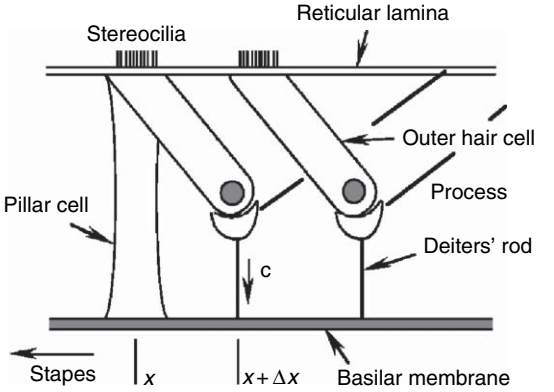

Figure 14 Side view of OHC showing the inclination (*x*–*z* plane). The end is supported by the cup of Deiter's cell, which has a rod providing mechanical attachment to the BM and a phalangeal process providing attachment to the RL. Inward shear of the stereocilia at the point x causes hyperpolarization of the OHC, which causes an elongation of the OHC, resulting in upward displacement of the RL and downward displacement of the BM. Because of the OHC inclination, this is a downward push on the Deiter's rod at the point $x + \Delta x$, "feed-forward". Because of the inclination of the phalangeal process, this rod will be pulled upward by an elongation of the OHC at the point $x + \Delta x_2$ which is a negative "feed-backward".

feature is that the shear on the cilia at the distance from the stapes given by x causes a push on the BM at the distance $x + \Delta x$.

Generally an active system with sensors and actuators that deliver energy to the system, which affects the input–output relation, is called feedback. For a system consisting of an input and output connected by a chain of processes, a sensor at one point that causes actuation at a preceding point in the chain, is called feedbackward, while a sensor that causes actuation at a subsequent point in the chain is called feedforward.

In birds and other nonmammals there is no motility and no stiff connection between the receptor cells and the BM. However, the hair bundle itself can have spontaneous oscillations and apparently is the source of a significant feedback of energy into the response. In this section we focus on the possible role of the OHC motility for mammals.

The structure of the OC shown in Figure 14 is elastic with the multiple attachments, so the elongation of a single OHC causes a ripple effect of loading of the BM in both directions. de Boer E. and Nuttall A. L. (2003) use a novel approach and take this into account with an array of impedances at different distances. The amplitudes of these feedforward and feedbackward elements are computed for a best fit with the experimental measurements of BM response, using the 3D calculation for the fluid. Here we offer a direct physical interpretation of a simpler version.

Another feature is that the fibers of the BM are in a sandwich in the PZ, then flatten to one layer in the arcuate zone (AZ) between the outer pillar (OP) and the inner pillar (IP). Since the bending stiffness D of a plate depends on the cube of the thickness, the BM AZ has roughly one-twenty-seventh of the stiffness of the PZ. Thus the OP offers significant support of the BM. Consequently, a simple model is the following sequence.

A downward pressure on the PZ, consisting of a positive fluid pressure p_F in the SV and an effective pressure from the Deiter's rods p_R causes a shear force on the OP foot of magnitude $(2p_F + p_R)b/2$ at the distance x from the stapes. The shear on the OP foot is roughly equal to the shear on the OHC cilia, if the details of the OC fluid-elastic motion are ignored. The shear is in the inhibitory direction and causes expansion of the OHC. The tendency of the OHC to expand causes a compressive force in the Deiter's rods, which is a downward force on the BM represented by the effective pressure p_R.

However, this occurs at the distance $x + \Delta x$. An equal and opposite force acts upward on the RL. Since this is more compliant, the displacement is more than for the BM, as shown in measurements in the cochlea and by calculations with the model in Figure 13. This upward displacement of the RL causes a tension in the phalangeal process, and an upward pull of the Deiter's rod. The equation for this is,

$$p_R(x+\Delta x,t) = \alpha[2p_F(x,t) + p_R(x,t)] - \alpha_2[2p_F(x+\Delta x_2,t) + p_R(x+\Delta x_2,t)]. \quad [32]$$

Thus the rod at the point $x + \Delta x$ is compressed by the OHC whose apex is at the point x by an amount proportional to the total pressure on the membrane, fluid plus rod, at x. So this is a positive feedforward with the amplitude α. The rod is also pulled by the phalangeal process by an amount proportional to the total pressure on the membrane at point $x + \Delta x_2$. So this is a negative feedbackward.

If the solution is used in the form eqn [27] with the assumption that Δx_2 and Δx are small, then eqn [32] becomes,

$$p_R e^{-jm\Delta x} = \alpha[2p_F + p_R] - \alpha_2[2p_F + p_R]e^{-jm\Delta x_2}, \quad [33]$$

with which the rod pressure p_R can be written in terms of the fluid pressure, so the total pressure becomes,

$$2p_F + p_R = \frac{2p_F}{1 - \alpha e^{jm\Delta x} + \alpha_2 e^{-jm(\Delta x_2 - \Delta x)}}. \quad [34]$$

Adding this feedforward and feedbackward to the previous eqn [29] for the dimensionless wave number yields,

$$\tilde{m} = \frac{8}{\pi} \times \frac{\tilde{\omega}^2}{\left[\tanh\tilde{m} - (1 + j\tilde{\omega}\gamma/\tilde{m}^2)^{-1/2}\right][1 - \alpha e^{j\tilde{m}\Delta\tilde{x}} + \alpha_2 e^{-j\tilde{m}(\Delta\tilde{x}_2 - \Delta\tilde{x})}]}. \quad [35]$$

Expanding this for small values as for eqn [30] gives the real and imaginary parts,

$$\mathrm{Re}(\tilde{m}) \approx \frac{8}{\pi}\tilde{\omega}^2\left[1 + \frac{1}{\sqrt{2\tilde{\omega}\gamma}}\frac{8}{\pi}\tilde{\omega}^2 + \alpha - \alpha_2\right], \text{ and} \quad [36]$$

$$\mathrm{Im}(\tilde{m}) \approx -\left(\frac{8}{\pi}\tilde{\omega}^2\right)^2\left[\frac{1}{\sqrt{2\tilde{\omega}\gamma}} - \alpha\Delta x - \alpha_2(\Delta x_2 - \Delta x)\right]. \quad [37]$$

Thus the feedforward and negative feedbackward tend to cancel in the real part. However, the positive feedforward and the negative feedbackward add to decrease the damping due to the fluid viscosity. In calculations it is far better to use the complete

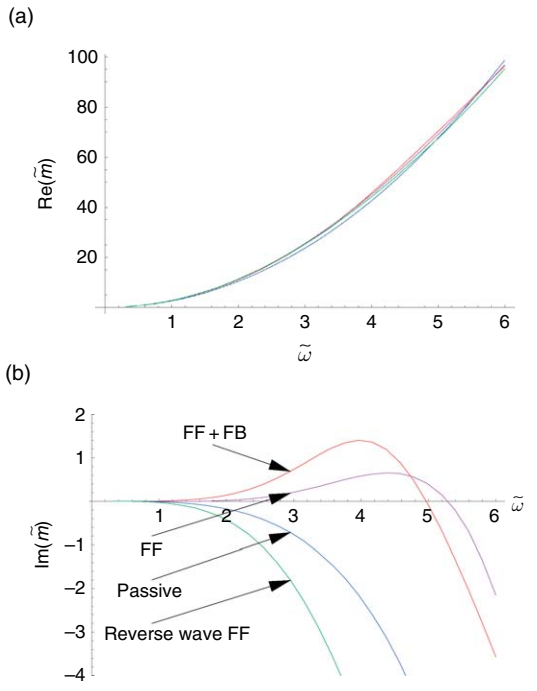

Figure 15 Wave number $\tilde{m}$ as a function of frequency $\tilde{\omega}$ from Equation xx. The curves "FF + FB" are for the feedforward due to the OHC inclination and the negative feedbackward due to the reverse inclination of the phalangeal processes, with parameters $\gamma = 10^5$, $\Delta\tilde{x} = 0.02$, $\Delta\tilde{x}_2 = 0.07\alpha = 0.08, \alpha_2 = 0.02$. The curves "FF" are with the effect of the feed-backward set to zero, $\alpha_2 = 0$. The curves "passive" are for both active effects turned off, $\alpha_2 = 0$ and $\alpha = 0$. Finally the curves "reverse FF" are for the traveling wave moving toward the stapes with $\Delta\tilde{x} = -0.02$ and $\alpha_2 = 0$. (a) The real part shows rapid accumulation for $\tilde{\omega} > 1$ and little sensitivity to feed-forward or feed-backward. (b) The imaginary part provides the effective damping of the wave, which is highly sensitive. The feed-forward push of the OHC causes a region of positive values, i.e., negative damping. The addition of the feed-backward "pull" of the phalangeal processes increases and sharpens the negative damping. For a wave in the reverse direction, the damping is increased by both effects. So the forward and backward waves are not the same.

relation (eqn [35]) and solve for the wave number iteratively. Results from this are shown in Figure 15. The real part of $\tilde{m}$, the spatial integral of which gives the phase, is not sensitive to the values for the parameters. However, the imaginary part of $\tilde{m}$ has dramatically different behavior. For the passive case, with both feedforward and feedbackward set to zero, the fluid viscosity provides the only damping. This is rather negligible for frequencies less than BF ($\tilde{\omega} < 1$), but increases rapidly for higher frequencies, and gives the rapid high-frequency decay in Figure 12(a). When feedforward is turned on with $\alpha = 0.08$, eqn [37] shows that the damping is decreased, but the full solution in Figure 15 shows that the imaginary part of $\tilde{m}$ actually is positive for a range of frequencies above BF. This can be interpreted as a negative damping due to the input of energy from the OHC motility. When the negative feedbackward is added, the positive range of the imaginary part of $\tilde{m}$ is decreased and sharpened.

With the approximation (eqn [32]), the details of the OC can be neglected and the transmission line model (eqn [19]) used. The effect is just a modification in the BM volume stiffness,

$$K_{\mathrm{Vol}}(x) \leftarrow K_{\mathrm{Vol}}(x)\left(1 - \alpha(x)e^{jm(x,\omega)\Delta x} + \alpha_2(x)e^{-jm(x,\omega)(\Delta x_2 - \Delta x)}\right). \quad [38]$$

Near the BF the changes in impedance is due to an apical shift in resonance for the low-level active case, but the phase change is small (Yoon, Y. J. *et al.*, 2006). This indicates that the zero crossings of the time domain response for the high-level passive case and the low-level active case will be nearly invariant. This suggests that force generation by OHCs in the feedforward formalism satisfies the near-invariance of fine time structure of the OC response predicted by Shera C. A. (2001).

The modification of BM stiffness is also valid in the 1D approximation (eqn [20]) and the 2D formulation (eqn. [23]) with the caveat that the stiffness may not be physical, as discussed above. Thus the feedforward causes a decrease in the effective partition stiffness and a negative damping. This is significant in the short wavelength region and corresponds to a significant input of energy into the traveling wave. For very short wavelengths, however, the fluid viscosity dominates.

The results for the 1D model for $\alpha_2 = 0$ (Geisler, C. D. and Sang, C., 1995) are excellent. The motility of the OHC saturates, which is represented by multiplying the factor α with a saturating function dependent on amplitude. The result for the dependence of the BM amplitude on input sound amplitude for the 3D model of the chinchilla cochlea is in Figure 12. The simulation results compare very well with other experimental measurements, capturing several nonlinear features observed in BM responses. These include compression of the response with stimulus level, two-tone suppressions, and generation of harmonic distortion and distortion products (Lim, K. M. and Steele, C. R., 2002). Transient click response has also been considered

(Lim, K. M. and Steele, C. R., 2003). The simulation results exhibit some of the characteristic nonlinear behavior of the BM commonly observed in experimental measurements, such as significant amplification and sustained ringing in the transient response at low stimulus levels. The simple feedforward mechanism is able to capture the properties of the active process in the cochlea without a second filter or resonance. All parameters are biologically based, with the feedforward needing only the inclination of the cells, assumed to be 30°, and the maximum value of α taken as 0.35 for the 3D calculation, which is modest.

The advantage of the distributed feedforward system should be appreciated. All the sensors and actuators are turned on, without the need for a "Maxwell's demon" to turn on the amplification where it is needed (Shera, C. A. and Guinan, J. J., Jr., 1999). For the long wavelength region, it has the effect of a small shift in the stiffness of the partition, but near BF, the negative damping is turned on with amplification of the signal of 40 dB or more. Then past BF there is little effect, and the high frequency fall-off is the same as for the passive case (Figure 12(a)). The assumption is that the OHC motility functions cycle by cycle without restriction on frequency, that is, α is independent of frequency. Whether the OHC actually performs this is a subject of current investigation in several laboratories.

3.10.6.3 Time Delay versus "Feedforward"

Similar to de Boer E. and Nuttall A. L. (2003) we ask for the time delay that would have the same effect as the spatial feedforward and feedbackward. With a time delay Δt in the pressure delivered to the BM from the OHC, eqn [32] is replaced by,

$$p_R(x, t + \Delta t) = \beta[2p_F(x, t) + p_R(x, t)]. \qquad [39]$$

The wave number-frequency relation eqn [35] is then,

$$\tilde{m} = \frac{8}{\pi} \frac{\tilde{\omega}^2}{\left[\tanh\tilde{m} - (1 + j\tilde{\omega}\gamma/\tilde{m}^2)^{-1/2}\right][1 - \beta e^{-j\tilde{\omega}\Delta\tilde{t}}]}, \qquad [40]$$

in which the dimensionless time delay is $\Delta\tilde{t} = \omega_{ref}\Delta t$. Expanding the wave number for small β and $\tilde{\omega} > 1$ as for eqn [35] gives the real and imaginary parts,

$$\mathrm{Re}(\tilde{m}) \approx \frac{8}{\pi}\tilde{\omega}^2\left[1 + \frac{1}{\sqrt{2\tilde{\omega}\gamma}}\frac{8}{\pi}\tilde{\omega}^2 + \beta\cos\tilde{\omega}\Delta\tilde{t}\right], \text{ and} \qquad [41]$$

$$\mathrm{Im}(\tilde{m}) \approx -\frac{8}{\pi}\tilde{\omega}^2\left[\frac{1}{\sqrt{2\tilde{\omega}\gamma}}\frac{8}{\pi}\tilde{\omega}^2 + \beta\sin\tilde{\omega}\Delta\tilde{t}\right]. \qquad [42]$$

Since β is positive, a small time delay *increases* the damping. The time delay must be tuned with $\Delta\tilde{t} > \pi$ for a decrease in the damping that corresponds to an energy input to the wave around the normalized BF $\tilde{\omega} \approx 1$. Another possibility is to make $\Delta\tilde{t} < 0$, to obtain negative damping for small time delays without tuning. However, this is a noncausal event, since what occurs at future time is having an effect at present time, as pointed out by de Boer E. and Nuttall A. L. (2003). with a different approach.

The stability can be examined by considering not a cochlea, but a simpler system consisting of a tube with constant properties over a finite length with a zero condition at the end $\tilde{x} = \tilde{L}$. The solution (eqn [27]), with forward and backward waves, provides the transfer function relating pressure at the general point x to the input pressure at $x = 0$,

$$\frac{\bar{p}(x)}{\bar{p}(0)} = \frac{e^{-j\tilde{m}\tilde{x}} - e^{j\tilde{m}_B(\tilde{x}-\tilde{L})-j\tilde{m}\tilde{L}}}{1 - e^{-j\tilde{m}_B\tilde{L}-j\tilde{m}\tilde{L}}}, \qquad [43]$$

where m_B is the wave-number for the backward traveling wave, defined by eqn [35] with the signs of Δx and Δx_2 changed. The poles are the zeros of the denominator at,

$$\tilde{m} + \tilde{m}_B = 2k\pi/\tilde{L}, \qquad [44]$$

in which k is an integer. For each k, this equation may be solved for the complex frequency. If the imaginary part of the frequency is negative, the solution is unstable in time. Remarkably, the feed-forward and feed-backward terms tend to cancel in the imaginary part, as can be seen by substituting the expanded eqns [36] and [37] into eqn [44]. Direct numerical calculations for the solution of eqn [44] support this, so it appears that the spatial delay expressed by the feedforward and feedbackward provides a stable system. Even when the imaginary part of the wave number is positive, as shown in Figure 15, the system remains stable. There is a limit to this, since for the gains $\alpha - \alpha_2 \to 1$, the stiffness becomes zero for small frequencies. A precise determination of the stability boundaries has not been carried out, but the gains used in Figure 15 can be increased by a factor of 3.9 until instability occurs. The zeros of the transfer function are the zeros of the numerator at,

$$\tilde{m} + \tilde{m}_B = 2k\pi/(\tilde{L} - \tilde{x}), \qquad [45]$$

which also have positive imaginary parts. So within certain limits, the feedforward system with a substantial gain in amplitude is stable and causal. This can be extended to the cochlea with variable properties. The condition (eqn [44]) becomes,

$$\int_0^{\bar{L}} (\tilde{m} + \tilde{m}_B) \mathrm{d}\tilde{x} = 2k\pi, \qquad [46]$$

which is more difficult to compute, but clearly with the same features.

In contrast, the forward and backward wave numbers are the same for the time delay system. Consequently, the solutions of eqn [39] show instability in time when the imaginary part (eqn [42]) is positive. Generally, feedback models incorporating time delay require additional components to prevent undesirable behavior. The measurements of Frank G. *et al.* (1999) show no time delay between the motile force and transmembrane potential. Therefore it appears most plausible that the frame structure in Figure 14 is for the purpose of the feedforward and negative feedbackward of energy into the traveling wave. Information on the exact inclination of the OHC and phalangeal process is lacking, but micrographs usually show a configuration similar to Figure 14. The one careful examination of this is from Karavitaki K. D. (2002), who finds in gerbil that the RL is nearly perpendicular to the OHC. Thus Δx is nearly zero. However, the Δx_2 is apparently equal to several OHC diameters, so the push–pull system works well.

3.10.6.4 Inner Hair Cell Excitation

In the preceding discussion an approximate relation (eqn [40]) is extracted from the physics of the OC, leaving only a modification of the BM model. Subsequently the details of the OC are avoided. However, the purpose of the OC is to provide the proper excitation of the IHC. The IHC cilia are not attached to the overlying tectorial membrane and are subject to the mechanical force of the fluid motion, which is dependent on the response of the entire structure of the OC. Consequently, the modeling of the OC is the subject of numerous recent studies. Böhnke F. and Arnold W. (1998) provide the most detailed FEM model, but without fluid. Kolston P. J. (1999) has inviscid fluid but with geometric simplification of the OC structure. Hubbard A. E. *et al.* (2003), Grosh K. *et al.* (2004), and Mountain D. C. and Hubbard A. E. (2006) use other geometric simplifications. Cai H. and Chadwick R. (2002), Andoh M. and Wada H. (2004), and Steele C. R. and Puria S. (2005) use detailed FEM models with realistic geometry and stiffness properties for the components.

As discussed by these authors, there is growing awareness that the flow of the fluid in the regions of the OC is important. Billone M. and Raynor S. (1973) provide perhaps the first careful analysis of the flow around the IHC cilia. One must keep in mind that in the hearing organ in lizards, there is considerable variety but always a group of receptor cells without a TM and with tall cilia free in the fluid. Freeman D. M. and Weiss T. F. (1990) have extensively investigated the mechanical behavior of these cilia through the relevant frequency range 1–3 kHz. It is of interest that the neural tuning and otoacoustic emissions from these receptor cells are similar to mammalian for the same frequency (Manley, G. A., 2006), without the TM, OHC motility, Deiter's cells, etc., that seem to be so important for mammals. For mammals, a feature recently established by Edge R. M. *et al.* (1998) is the proximity of the Hensen stripe, a protrusion of the tectorial membrane, to the tip of the IHC cilia, as indicated in Figure 15.

Nowotny M. and Gummer A. W. (2006) provide a breakthrough with measurements of the lower surface of the TM and the upper surface of the RL during electrical stimulation. They find that these surfaces do not remain parallel, as usually assumed. The calculation for the full elastic structure shows this as well. As can be seen in Figure 13, the region L1, near the IHC cilia between the TM and RL, opens with displacement of the BM toward ST. This tends to pull fluid in from the IS past the IHC cilia. Just how much depends on the relative stiffness of the TM and the proximity of the Hensen stripe (HS). Putting this together gives the effects on the phase of IHC excitation given in Table 5. The phase measured in neurons from the IHC in the middle and upper turns typically show for low frequencies something close to case 2, with a change toward case 1 as frequency increases (Cheatham, M. A. and Dallos, P., 1999). In the base with a relatively stiffer TM, Ruggero M. A. *et al.* (2000) report values similar to cases 3 and 4.

A strong mechanical nonlinearity comes from the restricted flow between the cilia, TM, and Hensen stripe (Steele, C. R. and Puria, S., 2005). A result of this is in Figure 17, which shows the tension in the tip link compared to the driving pressure, positive in the ST. Two peaks of the tension occur in each cycle of the pressure for a pressure level corresponding to

Table 5 Effects on phase of IHC tip-link tension for BM motion toward the ST, for which the pillar head and base of the cilium move radially outward. Cases 1 and 2 prevail for a soft TM, while cases 3 and 4 prevail for a stiff TM

Case	*Cause*	*Mechanism*	*Effect on IHC neurons*	*Phase*
1	Small gap with HS (or high frequency), cilium nearly sticks to HS	Tip lags the base, causing a decrease in tip-link tension in phase with the BM displacement.	Inhibition	0°
2	Large gap with HS and TM (or lower frequency), cilium is pulled through fluid	Tip lags the base, causing a decrease in tip-link tension in phase with the BM velocity.	Inhibition	90°
3	Small gap with HS, area of region L1 increases, cilium nearly sticks to HS, so L1 has negative pressure	Outward pressure on the cilium, causing an increase in tip-link tension in phase with the BM displacement.	Excitation	180°
4	Large gap with HS, area of region L1 increases, so fluid flows from IS into L1	Outward pressure on the cilium, causing an increase in tip-link tension in phase with the BM velocity.	Excitation	270°

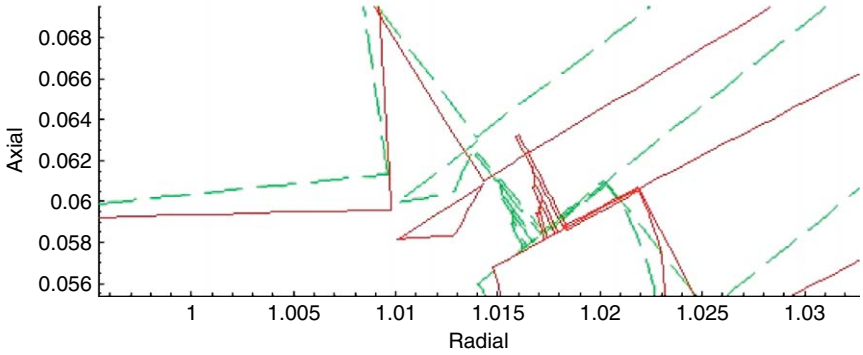

Figure 16 Close view of IHC cilia for guinea pig apex. The Hensen stripe (HS) is the triangle attached to the tectorial membrane above. The dashed lines show the undeformed configuration, with the tip of the IHC cilia near the HS. The solid lines show the deformed configuration due to static pressure loading toward ST, greatly amplified. The radial and axial distances are in mm.

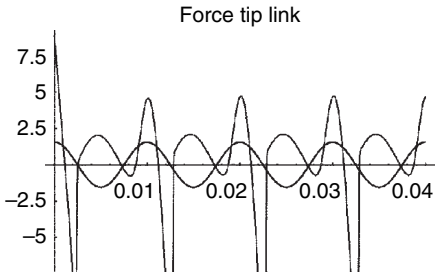

Figure 17 Nonlinear solution for the force in the tip link at the guinea pig base at 100 Hz. Around 90 dB SPL, two peaks of force (nonlinear curve) occur per cycle of ST pressure (cosine curve). This offers one possible explanation for the 180° change in phase and peak splitting sometimes observed in auditory nerve fibers (Kiang 1990).

around 90 dB SPL. For lower sound pressures, the peak that is out of phase with the pressure is the dominant one, and for higher sound pressures the only remaining peak is the one in phase with the pressure. This is remarkably close to the behavior of auditory neurons sometimes observed (Kiang, N. Y., 1990). A common expectation is that velocity of the BM toward the ST will cause the IHC cilia to be swept by the fluid in the inhibitory direction (to the left in Figure 13) (Figure 16). However, it seems that almost any phase of excitation is possible, depending on the specific geometry and relative stiffness properties. In the static response shown in Figure 13, the subtectorial fluid region L1 is seen to open with BM

displacement toward the ST. This will cause a fluid flow into L1 from the inner sulcus (IS) that will bend the cilia in the excitatory direction. BM motion toward the SV then is inhibitory. However, as the amplitude increases, the tall cilia are constrained by the Hensen stripe while the RL still moves to the left in Figure 13. This causes tension in the tip links seen as the in-phase peak in Figure 17.

3.10.7 Summary of Some Issues

Rapid development in measurement and computational techniques related to auditory biomechanics is ongoing. Perhaps the following issues soon will be completely resolved.

3.10.7.1 Motion of the Tympanic Membrane for High Frequencies

The simple model for the middle ear has the tympanic membrane acting as a rigid, massless piston. However, instead of piston-like behavior, surface displacement measurements have revealed multiple modes of vibration for frequencies above a few kilohertz (Tonndorf, J. and Khanna, S. M., 1972). This has provoked considerable discussion. A recent explanation offered in a preceding section is that the nonsymmetric material and geometric properties of the membrane provide mistuning without strong resonances. The consequence is a fairly uniform transmission of the pressure for the entire frequency range without the need for "woofer"-like or "tweeter"-like elements. Full validation for this notion is in progress.

3.10.7.2 Motion of the Ossicular Chain for High Frequencies

The nonmammalian vertebrates have a simple columella that transmits the tympanic membrane motion to the inner ear. In contrast, the mammals have a three-bone ossicular chain. In the simple model, this is represented by a simple lever with a fixed pivot point. However, measurements show that this is not the behavior for frequencies above a few kilohertz (Decraemer, W. F. *et al.*, 2003). The pivot point depends on frequency and the stapes wobbles, instead of directly providing a volume displacement of the cochlear fluid. The expectation is that this somehow permits the extension of the frequency range, but an explanation is totally lacking.

3.10.7.3 Bone Conduction

Hearing by bone conduction is of high clinical significance. There are many measurements showing that the volume displacements of the oval and round windows are exactly out of phase for air-conducted acoustic excitation, consistent with the two modes shown in Figure 7. All existing theory indicates that this is also the case for bone-conducted sound. However, measurements by Stenfeld S. *et al.* (2004) indicate that this is not the case for bone conduction. Indeed for some frequencies, the two windows are in phase. Thus there must be compliance in the cochlea not yet explained (often referred to as a third window) Dehiscence of the semi-circular canals has been clinically shown to produce a third window (Chien, W. *et al.*, 2007; Merchant, S. N. *et al.*, 2007; Minor, L. B. *et al.*, 2003). Sohmer H. and Freeman S. (2004) demonstrate that bone vibration generates acoustic pressure in the brain that can generate an auditory response. Estimates on the flow properties of the cochlear and vestibular aqueducts indicate that the compliance is too low to offer a reasonable acoustic pathway. Again, an explanation is totally lacking.

3.10.7.4 Traveling Waves

The traveling wave observed in the guinea-pig cochlea by Békésy G. (1960) was not anticipated by any theoretical consideration. There remain contrary opinions, for example Sohmer H. and Freeman S. (2004) consider their measurements as evidence against the existence of the traveling wave. The traveling wave does not occur in lizards and turtles, but most likely does occur in birds. For mammals, the evidence for the existence of the traveling wave seems overwhelming. We mention the direct *in vivo* observation of waves by Ren T. (2002), the close relation of BM displacement and neural excitation found in the same animal by Narayan S. S. *et al.* (1998), and the agreement in theory with the traveling wave, and experiment for the BM motion (Figure 12).

3.10.7.5 Cell Motility versus Stereociliary Forces

In nonmammalian hearing organs, there are no arches of Corti, Deiter's cells, or inner sulci as shown in Figure 13. Furthermore the cells similar to the OHCs cannot have somatic motility.

Nevertheless, in the responsive frequency range, the neural tuning is as sharp as in mammals, and evoked and spontaneous emissions occur very similarly to those in mammals (Manley, G. A., 2006). Crawford A. C. and Fettiplace R. (1985) discovered that the cilia on turtle hair cells have spontaneous activity, that is, they beat without external excitation. This mechanotransducer (MET) channel phenomenon is described as a Hopf bifurcation (Choe, Y. *et al.*, 1998). In all vertebrates, the cilia and transduction channels are similar. In mammals, is the energy of the active process generated by MET instability or somatic motility of the cell, or is it a combination? This is a subject of current investigation (e.g., Chan, D. K. and Hudspeth, A. J., 2005). Frank G. *et al.* (1999) discovered that the ratio of OHC motile force to transmembrane voltage remains constant to nearly 100 kHz without time delay, which supports the notion that motility is a unique feature of the OHC and must be important for mammalian hearing. Indeed the recent results on rat cochleas by Kennedy H. J. *et al.* (2006) offer evidence that both MET resonance and somatic motility are interacting.

3.10.7.6 Outer Hair Cell Roll-Off

The feedforward (and negative feedbackward) behavior discussed here depends on the force of motility of the OHC to be independent of frequency. However, the electrical properties of the OHC appear to be such that for a fixed amplitude of shear force on the cilia, there is a significant decrease in the intracellular potential at a frequency much less than the BF. Several laboratories propose more detailed analysis of intracellular or extracellular behavior that would maintain the effect of the motility for high frequencies. Without a more elaborate cell model, Baker G. J. (2000) and Grosh K. *et al.* (2004) use models with correct physical values for the electrical and mechanical properties of the OHC, but with a resonant TM, and find that the effects of the motility for high frequencies are preserved.

3.10.7.7 A Resonant Tectorial Membrane?

Many authors have used OC models with a strong resonance of the TM (e.g., Allen, J. B., 1980). Several laboratories have measured the properties of the TM, most recently Gueta R. *et al.* (2006) and Masaki K. *et al.* (2006). Details are different, but the general conclusion is that the TM is rather soft tissue, with an elastic Young's modulus in the 0.5–30 kPa range. Zwicker E. (1972) points out that squirrel monkeys and pigs have a huge difference in TM size. Such a difference for animals that have roughly the same frequency range of hearing makes a resonant TM seem unlikely. Nowotny M. and Gummer A. W. (2006) measure the TM response due to electrical stimulation and find no resonance for frequencies through the BF. So there are indications that the TM does not have a strong resonance.

3.10.7.8 Multiple Traveling Wave Modes

The common box model has the fast and slow waves indicated in Figure 7. However, each of the fluid spaces in the OC (Figure 13) can support an independent wave. Karavitaki K. D. (2002) offers measurements of motion of the OC that support the notion of multiple waves. As discussed by de Boer E. (2006) recent models, for example, Zhang L. *et al.* (1997) and Mountain D. C. and Hubbard A. E. (2006), have such a capability. The goal remains for a model of the OC with physically-realistic geometric and stiffness properties and with 3D viscous fluid, that can simulate the environment of the cilia for all frequencies. The expectation is that waves in the IS and tunnel space do play a significant role.

3.10.7.9 Stiffness Change Along the Cochlea

Almost every component of the cochlear cross-section has at one time or another been proposed as the fundamental resonance element. Most probably agree with Békésy G. (1960) that the BM has the strongest stiffness gradient and is the most likely candidate. The calculation in Table 4 shows that the modest variation in values of width, thickness, and fiber volume fraction of the PZ work together to explain the frequency range of the guinea-pig cochlea. The change in the volume compliance is five orders of magnitude. However, the direct measurement of the guinea pig cochlea by Békésy G. (1960) shows a change of three orders of magnitude, with a reasonable extrapolation to four orders of magnitude. Similarly, Zhang L. *et al.* (1997) find that the point load stiffness variation is inadequate to explain the frequency range in gerbil. With a different preparation, however, Emadi G. *et al.* (2004) find much more compliance in the apical region, which seems to fit the theoretical values from the geometry. The conclusion is that the soft cells covering the

BM make point load or volume compliance measurements difficult to interpret. As is often the case, a combination of theoretical and experimental approaches is needed.

3.10.8 General Summary

There are many acoustical and mechanical transformations performed by outer ear, middle ear, and cochlear structures. The components in the mammalian ear are more elaborate than those in nonmammalian vertebrates, with the advantage of a subsequently extended frequency range. The anatomic complexity of the mammalian ear ultimately results in greater functional capabilities. Some of quantifiable variables are sensitivity, frequency bandwidth, frequency resolution, dynamic range, and sound localization. The structures that lead to these capabilities do so given the available biological materials, space constraints within the skull, and limitations imposed by biophysics.

Several fundamental biophysical principles provide the means for obtaining the proper mechanical forcing of receptor cells in the inner ear. Each of the transformation steps can be described by a basic principle that can be readily understood using computational biomechanics. The objective of each transformation is to preserve the sound relevant to the species for the stated functionality. Each implementation is, however, much more complicated and involves biomechanical principles that are not all well characterized, are yet to be implemented in any man-made device, and are not free from controversy.

Less controversial is the spatially dependent transformation of sound by the pinna and the ear canal. The next step is the impedance alleviation between the air and fluid of the cochlea, which requires an area change provided by the eardrum and stapes footplate. It is not possible to have rigid, massless pistons for this purpose, so the tympanic membrane is an elaborate vibrating system with mistuning of the different radial sectors, each with significant resonances for frequencies over about 2 kHz. The ensemble, however, delivers a fairly smooth pressure to the ossicular chain. In the ossicular chain, the principle of a lever advantage is also readily grasped, but the chain does not behave as a simple lever for higher frequencies (>2 kHz) An adequate understanding of how the pressure is transmitted to the cochlea has yet to be attained.

In the cochlea, the local resonance at the BF is easily calculated for the BM immersed in fluid and soft cells. The reality of the transmission of the pressure to this point involves the fast and slow traveling waves, with their respective long and short wavelengths. The BF is not really a resonance in the sense of a set of tuned strings, but rather a point of transition to very short wavelengths. The actual BF location depends on fluid viscosity, width of the partition with respect to the BM, and sound level. The enhancement of the traveling wave by the active process for low levels of sound remains a subject of contention. The simplest model of feedforward provided by the geometry and the motility of the OHC appears to explain much. Such a distributed system of sensors and actuators is effective in enhancing the BM response near the BF. Finally, the transformation from BM motion to excitation of the IHC has the simple explanation of cilia being dragged through fluid. The details of the environment of the cilia and the proximity of the Hensen stripe make the actual cilia-fluid response much more complicated. Calculations for low frequencies have a resemblance to measurements in the IHC and in the neurons of the auditory nerve. However the full effect of the complex geometry for the full range of frequencies and amplitudes has yet to be examined. It is safe to predict that other mechanical design features are present in the OC to obtain the proper excitation of the IHC, which are not yet anticipated. The interplay between physiological measurements and bio-computational models helps to elucidate the knowns from the unknowns and thus provides a path toward greater understanding.

Endnotes

[1] The work for the absolute threshold of hearing ($p^2/\rho c \times \text{area} \times \text{time}$) is easiest to estimate at the tympanic membrane, and it is about 6×10^{-18} J for humans, using a threshold of hearing of $p = 15\,\mu\text{Pa}$ (−3 dB SPL), pars tensa area $= 55\,\text{mm}^2$, $\rho = 1.18\,\text{kg m}^{-3}$, $c = 344\,\text{m s}^{-1}$, and time $= 0.2$ s. If we assume that there is a loss of a factor of two

between the middle ear and hair cell detectors, the threshold of hearing becomes about 3×10^{-18} J.

[2] A dark-adapted eye requires 90 photons within 0.1 s to perceive a flash. However, the estimate is that only 10% of the photons entering the eye actually reach the cones, so that gives about 10 photons necessary for the perception (Hecht, C. *et al.*, 1942). The energy of a single photon in the middle of the visible spectrum (hc/ν) is 4×10^{-19} J, using $h = 6.6 \times 10^{-34}$Js, $c = 3 \times 10^{8}\,\mathrm{m\,s^{-1}}$, and $\nu = 500 \times 10^{-9}$ m. Therefore, for 10 photons the energy is 4×10^{-18} J.

[3] It has been observed for some time that the threshold of hearing in subjects can have quasi-periodic peaks and valleys. However, the mechanism may be related to nonlinear properties of the cochlea at low levels and internal reflections leading to standing waves.

[4] Here it is assumed that the middle-ear cavity pressure at the round window is negligible, which is the case in normal ears. In pathological ears the pressure at the oval and round windows maybe more comparable, due to acoustic coupling, and thus the important determining variable there is the pressure difference between the two windows (Merchant, S. N. *et al.*, 1997).

[5] The specific impedance was calculated as the measured cochlear input impedance Zc times the footplate area. In humans the average magnitude of Zc is $2^{1/2} \times 21 \times 10^{9}\,\mathrm{kg\,s^{-1}\,m^{-4}}$ and the average footplate area is $3.21 \times 10^{-6}\,\mathrm{m^2}$ (Aibara, R. *et al.* 2001). The $2^{1/2}$ is to convert the peak velocity to rms velocity.

[6] The one exception to this is the recent finding that the concave-eared torrent frog species listens to mating calls that are present above 20 khz (Feng, A. S. *et al*., 2006).

[7] The reciprocal of this can be found in loudspeaker designs. If one takes an isolated loudspeaker (the output driver) it would operate as a dipole generating nearly equal and opposite signals from the two sides that would tend to cancel in the far field. To increase the acoustic output of a speaker driver, it is almost always placed in a cabinet that prevents cancellation from the opposite phase.

Glossary

abneural A direction on the basilar papilla. Away from the side of the papilla containing the auditory nerve.

adenosine triphosphate (ATP) The source of energy in living cells.

columella A small, thin columnlike structure that transfers vibrations between the tympanic membrane and the fluid-filled basilar papilla.

farfield In acoustics, the region of a sound field, far from the source, in which sound propagates as a plane, progressive sound wave.

gnathostomes Jawed vertebrates.

homologous Characters in different species who were inherited from a common ancestor and thus share a similar ontogenetic pattern.

hyomandibular Pertaining both to the hyoidean arch and the mandible or lower jaw; as, the hyomandibular bone or cartilage, a segment of the hyoid arch which connects the lower jaw with the skull in fishes.

lagena The lower, posterior, and outer chamber of the inner ear projecting from the sacculus, probably responsible for hearing. Usually an otolith organ.

monotreme A primitive, egg-laying mammal.

nearfield In contrast to the farfield, a region close to a sound source where acoustic particle motion is largely due to hydrodynamic flow (fluid flow), rather than as part of a plane, progressive sound wave.

octaval Referring to the VIII cranial nerve, or auditory nerve.

otolith organ An organ of the ear characterized by a sensory epithelium overlain by an otolith, or substantially calcium carbonate ear stone operating as a restraint structure.

otophysans A sort of teleost fish having an efficient mechanical connection between the swimbladder and the ear known as Weberian ossicles.

sarcopterigians The three modern groups of lobe-finned bony fishes – the coelacanths, lungfishes, and tetrapods (amphibians). All have fleshy fins or limbs.

stereovilli The hairs of hair cells. The part of the hair cell, the deflection of which causes transduction, or the conversion of mechanical energy to electrochemical energy.

tectorial Pertaining to the structures of the ear that restrain the tips of the stereovilli so that they may be deflected by relative motion between the hair cell body and the tectorial structure.

telencephalic Pertaining to the most recently evolved portions of the brain (forebrain).

tetrapodomorphs Vertebrates having four legs and four feet.

thalamic Anatomical structure of the forebrain that connects brainstem structures with cerebral cortex.

tonotopic organization Organization of the ear or brain in which sound frequencies are spatially sorted and isomorphically projected.

vestibular Pertaining to the organs of the sense of balance.

Weberian ossicles In otophysan fishes, a series of bones connecting the ear and swimbladder, enhancing sound pressure sensitivity and upper hearing range.

This chapter summarizes what is currently thought about the evolution of the middle and inner ear of vertebrates. What is thought on this topic has varied over time, depending on the orientation of the author with respect to evolution in general, and auditory system evolution in particular. For example, the story of the evolution of the middle ear could be told by moving backward in time from the three-ossicle middle ear of humans (mammals) to the origins of this peculiar ossicular arrangement among early mammals, and then back through reptiles and early tetrapods, to the various fishes. The mammalian coiled cochlea could be treated similarly. This way of constructing a story emphasizes the unity of life (Dawkins, R., 2004). Another way to tell the story is through the history of all vertebrates, from fishes, to paleozoic tetrapods, to the great diversifications of species about 250 million years ago (mya) when there appeared crocodiles, dinosaurs, turtles, mammals, modern amphibians, and teleost fishes (Manley, G. and Clack, J., 2004). This is a more satisfying orientation to the evolutionary stories that extols the diversity of life (Dawkins, R., 2004). I choose this orientation in part because one particular extant form (e.g., the mammalian middle ear) is not portrayed as an inevitable evolutionary endpoint, and in part because it presents the various extant middle ears as alternative solutions to a problem and not as imperfect approximations of the mammalian (human) type.

What follows is one view of the evolution of middle and inner ears among vertebrate animals. This view arises primarily from the recently published volume, *Evolution of the Vertebrate Auditory System* (Manley, G. *et al.*, 2004), which represents the most recent and comprehensive treatment of this complex topic. The following depends heavily on this source, and is in some ways a selective summary of it.

The gnathostomes comprise the early fishes, splitting into three groups, lobe-finned fishes leading to Coelacanth (*Latimeria*) and the tetrapods; ray-finned fishes leading to most modern fishes; and sharks and rays. The first vertebrate inner ears appeared among fishes, and the same could be said of middle ears with a generous definition of middle ear. Of course, there is only speculation on the origin of the first vertebrate ear that responded to sound, but it is likely to have developed very early on from an ear that was initially adapted as a vestibular organ, with typically vestibular frequency response (fractions of a hertz to 10 Hz, or so). Organs with presumed vestibular functions have been identified in all three groups of gnathostomes, so were likely present in their common ancestor. It is not known whether the auditory organs observed in living representatives of these three groups are homologous or convergent (independently evolved). An auditory organ cannot be identified by appearance in fishes because the main distinction between a vestibular and auditory organ is in the frequency response and filtering properties (Cortopassi, K. A. and Lewis, E. R., 1988) of its filters, and its projections to the central nervous system (CNS). Any otolith organ such as the saccule can respond to sound (acoustic particle motion) by transducing relative motion between the otolith (density of about 3) and the sensory epithelium (de Vries, H. L., 1950). This relative motion can be caused by a nearfield or farfield wave passing through the animal and bringing the tissues into motion. Due to its high inertia, the otolithic mass will lag the motion of the tissues and a relative motion will result. When the frequency of this disturbance becomes sufficiently high (e.g., 100 Hz), we can say that it is sound. The animal can be said to hear if it could be expected to respond to the source as an external entity (Lewis, E. R. and Fay, R. R., 2004). This primitive or shared mode of hearing operates in all extant species and is the basis for their hearing which is apparently present in all species. Motional sensitivity of otolith organs is high; behavioral and physiological responses can be evoked by 100 Hz displacements as small as 0.1 nm (Chapman, C. J. and Sand, O., 1974; Fay, R. R. and Edds-Walton, P. L., 1997).

Among fishes, the presence of a sense of hearing is to be inferred, in many cases where behavioral data are lacking, by the organization of the CNS. All fishes examined so far have a central auditory system organization analogous to mammals and other tetrapods (see Chapters 3.30, 3.49). There are several first-order medullar nuclei that project to the auditory nucleus of the midbrain directly and via secondary octaval cell populations (in all fishes examined so far; McCormick, C., 2001). There is at least one thalamic auditory nucleus (Lu, Z. and Fay, R. R., 1996), and several telencephalic auditory nuclei, although these are not well known. This organization is the hallmark of an auditory system in other vertebrates, and is presumed to have the same function among fishes. It is certainly not a central vestibular system.

Many freshwater species have special adaptations that make them pressure sensitive as well as directly sensitive to acoustic particle motion (Braun, C. and Grande, T., in press). These species are generally referred to as hearing specialists, and all are

characterized by a gas bubble or gas bladder that is brought into close association with the ear by a short or efficient transmission pathway. These specialists are thought to be more sensitive to sound and to have a wider bandwidth of hearing than the generalists (by definition, all other fishes). As described by Boyles law, these gas bodies change volume in response to sound-pressure fluctuation, and this motion is transmitted to the organ(s) of the ear where they engage the otolith or hair cell sensory epithelium in motion. These ears therefore respond in proportion to sound pressure and would even be expected to respond to a pressure maximum of a standing wave where the wave impedance is nearly infinite (Fay, R. R. and Popper, A. N., 1975). In the Otophysans (goldfish, carp, minnows, suckers, knifefish, and catfish), this transmission pathway is the Weberian ossicles, a series of modified ribs and vertebral arches that directly connect the anterior swimbladder with the perilymphatic system of the ear, and ultimately to the endolymphatic fluids of the saccular organ. Another way that the swimbladder can be brought into proximity with the ear is by way of forward extensions of the swimbladder, or swimbladder horns. These can be found in species of the Holocentridae, Gadidae (cods), Cichlidae, Notopteridae, Elopomorphidae, and Percomorpha. Finally, there are the peculiar ears of clupeids (herrings) (Blaxter, J. H. S. *et al.*, 1981) in which an air-filled chamber directly apposes the utricular organ, and the Mormyridae (African electric fish; Crawford, J. D., 1997) in which the paired saccules have attached private gas bladders. In these species, the saccule (or utricle in herrings) can probably be identified as an exclusively auditory organ. Within teleosts, novel mechanisms for enhancing hearing may have evolved over 20 times (Braun, C. and Grande, T., in press). It has been speculated that these hearing enhancements probably required rather quiet environments in which to evolve (Amoser, S. and Ladich, F., 2005). Throughout the evolution of fishes, hearing has been subserved by otolith organs (commonly, the saccule) and there is little indication of the development a specifically auditory papilla in fishes as developed in tetrapods. However, Fritzsch B. (1987) described an unusual sensory papilla that he identified with the tetrapod basilar papilla in the ear of the Coelacanth (Latimeria), one of the only surviving species of sarcopterigians (lobe-finned fish) that are tetrapod ancestors. However, it is not known whether this organ is homologous with the basilar papilla of tetrapods.

These, and other morphological specializations for enhanced hearing, have evolved and are still evolving among teleosts. Teleosts appeared in the late Triassic (225 mya) roughly along with crocodiles, dinosaurs, turtles, modern amphibians, and mammals. The earliest known Weberian ossicles first appeared during the late Cretaceous period (40–50 mya; Clack, J. and Allin, E., 2004). Thus, there is a long time separating the earliest fishes (420 mya) from the diversification of species that included the teleosts and the presumed development of the hearing specialists (an interval of about 350 million years). Thus, the hearing enhancements among fishes appeared much later than the development of the tetrapod tympanic ear.

The first tetrapodomorphs appeared in the fossil record in the late Devonian about 350 mya, and they continued to evolve for 140 million years before the great diversification of species during the late Permian. For most of this period, these tetrapods were amphibious, and probably spent a significant portion of their life underwater. Their tetrapod limbs served locomotion underwater, and on land probably served getting the animal from one body of water to another. Presumably, the tetrapod basilar papilla first appeared among these Paleozoic tetrapods as a new organ in the lagenar resess, between the saccule and lagena, but there is no fossil evidence regarding the first appearance of the basilar papilla. Nor is there evidence that these amphibians developed arial hearing until the Triassic period (appearance of tympanic ears in various groups), so this new organ must have functioned primarily in bone conduction and underwater hearing (see Chapter 3.14). The basilar papilla of turtles and the Tuatara (*Sphenodon*) are probably the closest organs in living species to the original basilar papilla of tetrapods (Wever, E. G., 1978). Based on the ears of these species, the original papilla was probably of small size (less than 1 mm), contained between 100 and 1000 hair cells, had both afferent and efferent innervation, was covered by a tectorial membrane, and had hair cell orientations in only one, abneural direction (Manley, G. and Clack, J., 2004). It did not receive input from a tympanic ear, however.

The evolution of the stapes or columella (formerly in fishes, the hyomandibular bone) had begun among Paleozoic tetrapods (e.g., *Acanthostega* and *Ichthyostega*); its size, orientation, and relation to other skull structures give clues to its possible functions in hearing. Originally, apparently, it fit into the early equivalent of the oval window, but

its function is a matter of speculation. It was too massive to function as a stapes does, but could have functioned in bone conduction as an inertial mass (analogous to an otolith) in a mechanical circuit involving the basilar papilla. However, a pressure release window analogous to the round window did not evolve until later, and independently in mammals, crocodiles, birds, and dinosaurs (Clack, J. and Allin, E., 2004).

Throughout the Carboniferous period (350–290 mya) two groups of tetrapods developed; the line leading to amniotes (reptiles, crocodiles, birds, and mammals), and the line leading to modern amphibians (temnospondyls and lissamphibians). The temnospondyls were the first animals thought to have a terrestrially adapted ear, with a narrow-shafted stapes and a skull embayment presumed to be tympanic (e.g., *Balanerpeton* from the early Carboniferous; Clack, J. and Allin, E., 2004). These temnospondyls are thought to be the first species to make sounds. An alternative hypothesis places lissamphibians and amniotes closer to lepospondyls, small tetrapods that did not develop a tympanic ear until the late Triassic (210 mya). In any case, lissamphibians are the frogs and toads (Anura), salamanders and newts (Caudata), and caecilians (Gymnophonia). Modern forms are all thought to be highly derived (specialized) compared to their earliest ancestors, with the Caudata probably most closely resembling their early ancestors (Smotherman, M. and Narins, P., 2004). The ears of anurans consist of an amphibian papilla, a basilar papilla, a macula neglecta, a lagena, and a saccular organ, among others. The anuran basilar papilla may be homologous to the basilar papilla of reptiles and birds, but in spite of having the same name, this is not settled. The amphibian papilla has no counterpart among amniotes, yet it is tonotopically organized, unlike the anuran basilar papilla. Primary afferents are narrowly tuned and represent filters of high dynamic order (Lewis, E. R., 1992), so these characteristics evolved independently among amphibians and amniotes.

Remarkably, a tympanic middle ear developed independently among all amniotes during the Triassic (2220–250 mya), affording each group (Synapsids, Lepidosaurs, and Archroaurs) an enhanced sensitivity to airborne sound (Clack, J. and Allin, E., 2004; see Figure 1). This, in turn, apparently caused a rapid and simultaneous development and differentiation of the basilar papilla characteristic of these groups toward their modern forms (Manley, G. and Clack, J., 2004). Crocodiles, alligators, and birds are the descendants of the Archosaurs. The basilar papilla of these groups is wide and elongated, covered by a mosaic of hair cells and a thick tectorial membrane. In birds, there can be as many as 50 hair cells per cross-section,

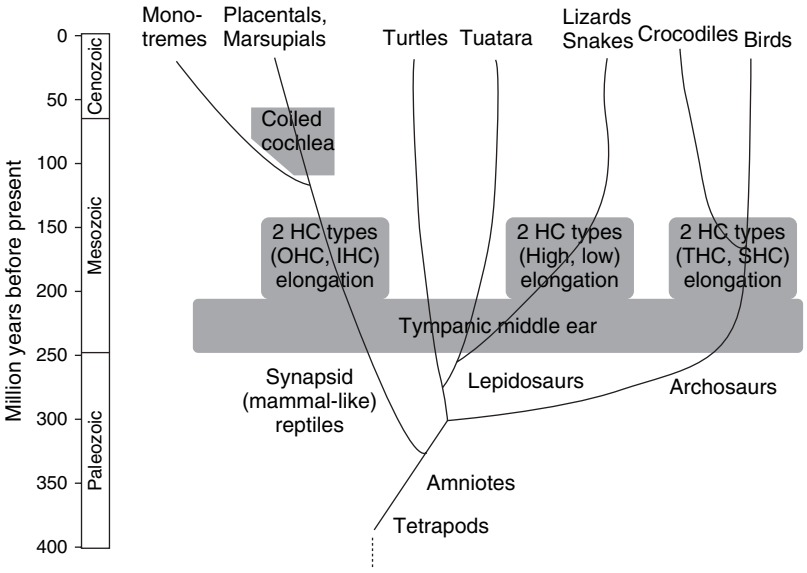

Figure 1 A family tree for amniote vertebrates emphasizing the independent evolution of the tympanic middle ear, and the independent development of two hair cell (HC) types. IHC, inner hair cell; OHC, outer hair cell; SHC, short hair cells; THC, tall hair cells. Reproduced from Manley, G. and Clack, J. 2004. An Outline of the Evolution of Vertebrate Hearing. In: Evolution of the Vertebrate Auditory System (*eds*. G. Manley, A. N. Popper, and R. R. Fay), pp. 1–26. Springer, with permission from Springer.

some so-called tall hair cells, and some short hair cells. Tall hair cells receive both afferent and efferent innervation, while short hair cells receive efferent but no afferent innervation. Apparently this dichotomy evolved independently and at the same time as inner and outer hair cells in mammals (late Triassic period).

Turtles represent their diapsid ancestors, and the Tuatara (lizard-like animal) is slightly later derived. The numerous species of lizards and snakes make up the most living descendents of diapsid lepisosaurs that developed during the Triassic. The basilar papillas of lizards is rather well described (Wever, E. G., 1978). It always has two types of hair cells; low-frequency and high-frequency. Low-frequency hair cells (<1 kHz) are primitive types derived from stem reptiles and snakes. High-frequency hair cells (up to 5 or 6 kHz) are more recently derived. These two types of hair cells arose independently of tall and short hair cells in birds, and inner and outer hair cells in mammals. The basilar papilla of iguanids is the most primitive. It consists of three areas; a central area of unidirectionally oriented, low-frequency hair cells (presumably representative of stem reptiles) flanked by areas of high-frequency hair cells on both sides, oriented in two, opposing directions. The central, unidirectional area is made up of hair cells that are electrically tuned to various best frequencies by virtue of particular membrane channels (Fettiplace, R. and Crawford, A. C., 1980). Extant lizards show remarkable diversity at the level of families, genus, and species (Manley, G., 2004). Surprisingly, this structural variation is not correlated with parallel functional variation; the peripheral anatomy is highly diverse among species, but the neurophysiology shows remarkable conservation of function and no comparable diversity (Manley, G., 2004).

Nonmammalian tetrapods all have a compound mandible consisting of many interrelated bones. The mammal mandible consists of the dentary bone alone, and the others of the complex jaw of mammal ancestors have been recruited into the new middle ear (angular, surangular, articular (malleus homolog), and preatricular) along with the quadrate (incus homolog), or are lost in mammals. This complex middle ear of mammals is probably responsible for the subsequent development of high-frequency hearing among mammals, but this capacity requires adaptations of the cochlea as well as of the middle ear.

The best-known early or stem mammal is *Morganucodon*, a small insectivorous animal of the late Triassic (200 mya). It is almost certain that this genus had a tympanic membrane; a malleus, incus, and stapes; and aerial hearing. Its cochlea has a finger-like shape, similar to that of birds. Rosowski J. J. (1992) has modeled the middle ear of *Morganucodon* as a mammalian microtype that was adapted to high-frequency hearing typical of some extant mammals. The elongated, coiled cochlea characteristic of modern placentals and marsupials (but not monotremes) appeared at least by the late Cretaceous (70 mya). So, it is thought that high-frequency hearing of modern mammals (well above 10 kHz) and echolocation capacities of some species, traits that set them apart from monotremes and all other tetrapods, appeared most definitely by this time (the late Cretaceous), and possibly earlier with *Morganucodon* during the late Triassic. High-frequency hearing predated a long, coiled cochlea.

Extant monotremes (platypus and echidnas) retain reptilian ear characteristics such as a short, uncoiled cochlea, the retention of a lagena at the distal end of the cochlea, and hearing probably no higher than 10 kHz. However, they have a three-ossicle middle ear that appears to have developed independently in monotremes and therian mammals (Rich, T. H. *et al.*, 2005), and the cochlea's internal structure is more similar to other mammals than to archosaurs (birds and reptiles) in having a clear distinction between inner and outer hair cells (Vater, M. *et al.*, 2004). The earliest known monotreme is from the early Cretaceous (140 mya), but the earliest known middle ear fossils are 115 million years old (from the Cretaceous period).

Recently, it has become clear that the mammalian cochlea is endowed with a unique mechanism for active amplification, motile outer hair cells that can feed back electrical-to-mechanical energy to basilar membrane motion. One mechanism identified in this process is prestin, a protein of the outer hair cell membrane that is capable of direct, rapid, electromechanical conversion without dependence on adenosine triphosphate (ATP; Zheng, J. *et al.*, 2000). It seems likely that prestin's functional role of active amplification appeared already in the first amniote ears (Manley, G. and Clack, J., 2004). Active amplification via the stereovillar bundle has been identified and analyzed in the saccular organ of bullfrogs (Hudspeth, A. J., 1997). While this organ has vestibular functions in amniotes, it functions as an organ of hearing in fishes and anurans (Lewis, E. R., 1992). Apparently, transduction channels on the stereovillar bundles cause a force on the bundle when they are

opened and closed. This general mechanism for fast stereocilliar motility has been observed in various hair cell systems, and appears to operate in the mammalian cochlea as well (Kennedy, H. J. *et al.*, 2003; Manley, G. and Clack, J., 2004). So, there seems to have been a parallel evolution of inner ear active amplification processes. The prestin mechanism is so far only identified with outer hair cells and the high-frequency hearing of mammals (well above 10 kHz).

In conclusion, one of the remarkable developments in our understanding of middle and inner ear evolution is the recent evidence for, and our willingness to accept, the ubiquity of parallel or independent evolution of many features of the auditory system. Not covered here is the story of the evolution of the CNS (Grothe, B. *et al.*, 2004), another example of parallel evolutionary trends among all vertebrates. In every vertebrate order the organization of the auditory CNS is analogous; it consists of multiple first-order medullar nuclei, several secondary nuclei, a lateral lemniscus, a midbrain auditory nucleus, thalamic nuclei, and telencephalic auditory areas. But all this analogy (including neurophysiological or functional analogy) has to be attributed to independent evolution because the evidence is against homology. Likewise, in the evolution of the middle and inner ears the recent evidence is inescapable that many features of vertebrate audition evolved independently. These features include the development of tympanic ears for aerial hearing; the development of two categories of hair cell; the three-boned middle ears of mammals; the inner ear organs themselves in fishes, amphibians, archosaurs, and mammals; mechanisms for frequency selectivity; and cochlear amplification. All this parallelism begs the question of what accounts for it. At least part of the answer must be that the requirements of auditory systems (the state demanded by the organism; Gans, C., 1992) are essentially similar for all species and for all time; the capacity to determine and perceptually segregate sources of sound, so that behavior may be appropriate with respect to them (Lewis, E. R. and Fay, R. R., 2004).

Glossary

arthropods Animals with segmented bodies and legs: insects, spiders, and crustaceans.

chordotonal organ Sensory organ found in insects and crustaceans. The name means long, thin structure, associated with hearing.

cilium, cilia Hairlike structures that form parts of many types of cells.

nematic Having molecules arranged in a linear, but not layered structure.

scolopale Twisted fence, a ring of electron-dense rods like the staves of a barrel.

tubular body Structure found in many arthropod mechanoreceptor neurons consisting of microtubules embedded in electron-dense material.

3.12.1 Introduction

Chordotonal organs are mechanosensory structures found in two of the three major classes of arthropods, insects, and crustacea (Graber, V., 1882; Howse, P. E., 1968; Moulins, M., 1976; Field, L. H. and Matheson, T., 1998). Arthropod mechanosensory neurons form two major groups, type I (cuticular) and type II (multipolar) (McIver, S. B., 1985; French, A. S., 1988). Type I neurons are bipolar, with cell bodies in the periphery between a single sensory dendrite and an axon that proceeds proximally to the central nervous system. They are closely associated with the exoskeleton, or cuticle, and innervate the hairs and bristles that cover many arthropods. In contrast, type II neurons have multiple sensory dendrites and are generally located in deeper structures such as muscles and internal organs.

Chordotonal organs contain type I sensory neurons. In insects, they are generally less directly connected to the exoskeleton than hairs or bristles. Instead, they are located below the cuticle, and detect relative movements of various body parts. In the case of joints in appendages, such as legs or antennae, this provides proprioception or gravity detection. In other cases the appendage is moved by currents in the air or water surrounding it, providing a sense of movements in the external environment. Chordotonal organs are often sensitive to rapid mechanical oscillations, making them vibration detectors and, for air-borne vibrations, organs of hearing. These include some elaborate hearing structures with comparable sensitivities and frequency ranges to vertebrate ears.

Less is known about crustacean chordotonal organs, although some have provided useful physiological models (Gamble, E. R. and DiCaprio, R. A., 2003). Crustacean chordotonal organs are more strongly associated with external mechanoreception, although nonchordotonal mechanosensory

innervation of sensory hairs in crustacea has also been reported (Crouau, Y., 1995).

3.12.2 Structures of Chordotonal Organs

General and specific structures of a variety of chordotonal organs have been described by light and electron microscopy (Howse, P. E., 1968; Moulins, M., 1976; Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). The central component is always a bipolar (type I) sensory neuron. The nomenclature is confusing because chordotonal sensory neurons are subdivided into type 1 and type 2, based on the form of the cilium (Figure 1; Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). Type 1 sensilla have long ciliary roots and a slender cilium with a dilation toward the distal end, whereas type 2 have reduced ciliary roots and the cilium expands distally with internal microtubules forming a tubular body.

The primary distinguishing feature of all chordotonal organs is the scolopale cell that surrounds the cilium, or several cilia, producing a dense set of intracellular scolopale rods, like barrel staves (Figure 1). Distally, the cilium is connected to an attachment cell and is embedded in an extracellular cuticular electron-dense structure forming a cap or tube. These forms are called mononematic or amphinematic, respectively (Graber, V., 1882; Moulins, M., 1976) reflecting the long, drawn-out form of the tube structure. Although type 1 and type 2 sensilla are generally associated with the cap and tube structures, respectively, chordotonal organs may contain more than one sensillum, of mixed types, embedded in the same distal structure. The terms monodynal and heterodynal refer to organs containing a single sensillum and multiple sensilla.

External to the cap or tube is an attachment cell, which connects the organ to the source of mechanical tension. However, tubes are often embedded in the external cuticle, which is presumed to provide the mechanical stimulation directly. Many fine ultrastructural details and significant variations exist within these broad patterns (Moulins, M., 1976; Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). Development, differentiation, and cell lineages of the various cells forming chordotonal organs have been reviewed by Field L. H. and Matheson T. (1998).

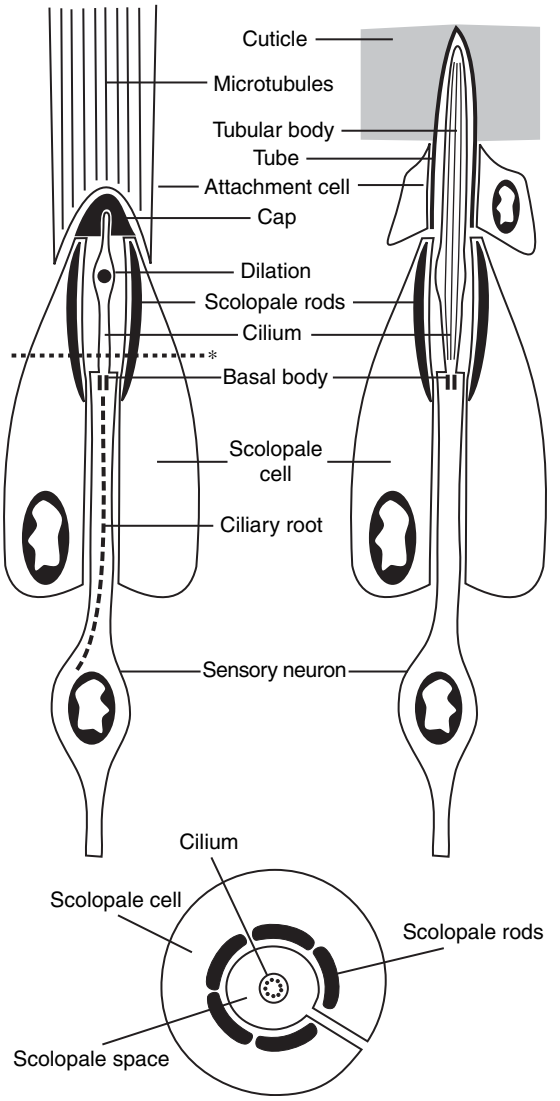

Figure 1 Chordotonal sensilla structures. Left: Type 1. Asterisk indicates the level of section shown in the lower figure. Right: Type 2. Note that other supporting cells are omitted for simplicity (based on material in Moulins, M. 1976; McIver, S. B., 1985; Field, L. H. and Matheson, T., 1998).

3.12.3 Locations and Functions of Chordotonal Organs

3.12.3.1 Major Functions

In insects, chordotonal organs are found in all major body regions (head, thorax, abdomen) and many appendages (antennae, mouthparts, legs, wings, ovipositors, cerci). Modalities include joint proprioception (connective chordotonal organs), substrate vibration (subgenual organs), sound (tympanal

organs) (Field, L. H. and Matheson, T., 1998), and infrared detection in the fire beetle (Mainz, T. *et al.*, 2004). Some organs are broadly homologous in many different species, such as the femoral chordotonal organ that detects femur–tibial movements and is involved in control of the leg musculature (Moran, D. T. *et al.*, 1975; Field, L. H. and Matheson, T., 1998; DiCaprio, R. A. *et al.*, 2002), and Johnston's organ in the pedicel (second segment) of insect antenna (McIver, S. B., 1985). Johnston's organs contains both type 1 and type 2 sensilla but they always terminate in one tube (amphinematic) ending. Johnston's organ is prominent in Diptera, with up to 20 000 sensory neurons in each male mosquito antenna, where they detect the sound produced by female mosquito wings (McIver, S. B., 1985).

3.12.3.2 Organs of Hearing

Sound sensitivity is known in many, but not all, insect groups. Organs of hearing occur in a wide variety of body locations in different species, including the mouthparts, thorax, abdomen, wings, and legs (Michelsen, A. and Larsen, O. N., 1985; Yack, J. E., 2004). Although some air movements are detected by long surface hairs, which are not chordotonal organs, most sounds are detected by structures based on chordotonal organs. The most elaborate of these use tympanal structures in the exoskeleton to collect and focus the sound vibrations onto sensilla. Tympanae are usually formed from the walls of trachea, which circulate gases within insect bodies (Michelsen, A. and Larsen, O. N., 1985; Yack, J. E., 2004).

Shaw S. R. (1994)suggested a model for the evolution of tympanal hearing organs in insects (Figure 2). In this model, chordotonal organs forming part of the vibration-detecting subgenual organ in the leg migrated to innervate the wall of an enlarged air sack in a leg trachea, increasing their sensitivity to vibration within the leg. This arrangement made the chordotonal organs sensitive to sound traveling through the tracheal system. Evolution to a true tympanal ear occurred by further enlargement of the air sack until it reached the exoskeleton, which thinned to form a tympanal membrane. Examples of these three stages exist in termites, cockroaches, and crickets (Shaw, S. R., 1994). Similar models could explain the occurrence of tympanae in other body regions.

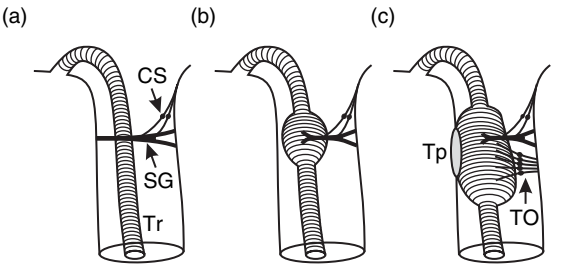

Figure 2 A model of the evolutionary development of tympanal hearing organs in insect legs. (a) Precursor state found in some termites. (b) Intermediate state found in cockroach. (c) Developed state found in some crickets. CS, chordotonal sensilla; SG, subgenual organ, Tr, trachea; TO, tympanal organ; Tp, tympanum. Based on material in Shaw, S. R. 1994. Detection of airborne sound by a cockroach 'vibration detector': a possible missing link in insect auditory evolution. J. Exp. Biol. 193, 13–47.

3.12.4 Sensory Biophysics

3.12.4.1 Mechanoreception in Arthropod Type I Mechanosensilla

Mechanoreception can be treated as a three-stage process (French, A. S., 1992): (1) coupling of the mechanical displacement to the membrane of a sensory cell; (2) transduction of mechanical stress in the membrane to ionic current through the membrane (receptor current) that changes the voltage across the membrane (receptor potential); and (3) encoding of the receptor potential into action potentials by voltage sensitive ion channels in the membrane. Encoding may be omitted where distances are short, or may occur in other cells that are synaptically activated by the primary receptor cell.

Chordotonal organs contain type I arthropod neurons, which are widely used as models of mechanosensation and provide a basis for understanding chordotonal biophysics. Most work has used insect or spider neurons with tubular bodies in the sensory dendrites, analogous to type 2 chordotonal sensilla. Coupling from external mechanical sources is not well understood in any type I system, although the consensus is that distortions of ~1–10 nm at the tip of the sensory dendrite lead to transduction (French, A. S., 1992). The tubular body may provide a rigid structure, against which external force can squeeze the dendrite membrane. However, destruction of the microtubules reduced but did not eliminate transduction (French, A. S., 1992; French, A. S. *et al.*, 2002).

The transduction step is believed to be due to mechanically activated ion channels in the dendrite

membrane. In some type I insect sensilla, the receptor current is driven by a potassium concentration and voltage gradient across the sensory dendrite that is maintained by metabolic pumping of potassium into an extracellular lymph space sealed by tight junctions (McIver, S. B., 1985; French, A. S., 1992), whereas some spider type I sensilla have a receptor current that is highly sodium selective (French, A. S. *et al.*, 2002). The identity of the mechanically activated ion channels is unknown in any receptor. Evidence that they are members of the TRP (transient receptor potential) channel family have been presented for *Drosophila* bristles (Walker, R. G. *et al.*, 2000), but there are also suggestions that members of the degenerin/acid sensitive ion channel families may be involved in spider mechanosensilla (French, A. S. *et al.*, 2002). Current models often include connections from the channels to both cytoskeleton and extracellular structures to provide mechanical stress (Walker, R. G. *et al.*, 2000; Gong, Z. *et al.*, 2004). Mechanically activated ion channels have been localized in spider sensilla, where direct extracellular recordings show that electrical activity is initiated at the distal dendrite tips (Gingl, E. *et al.*, 2004).

Type I neurons use sodium-dependent action potentials for axonal conduction (French, A. S., 1988). Several types of slowly and rapidly inactivating voltage-dependent potassium currents are found in insect and spider sensilla (Torkkeli, P. H. and French, A. S., 1995; French, A. S. *et al.*, 2002), but the dynamic properties of action potential encoding in spider sensilla can be explained by a model containing only voltage-activated sodium and delayed-rectifier potassium currents (French, A. S. *et al.*, 2002).

3.12.4.2 Mechanical Coupling in Chordotonal Organs

The complex morphology of chordotonal organs suggests mechanical functions for all or parts of the cilium, scolopale, cap, tube, and attachment cell. Field L. H. and Matheson T. (1998) discussed the mechanical properties of these structures, and the intercellular junctions and contacts that join them, to produce models of mechanical coupling. For mononematic sensilla, the attachment cell, cap, and scolopale are likely to be mechanically strong, and the primary stimulus is probably tension in the attachment cell. It is not clear if the scolopale acts as a rigid tube that transmits mechanical force from the cap to the basal body of the cilium, or if it forms a cage through which the cilium is pulled by the cap. Scolopale rigidity is not clearly established (Field, L. H. and Matheson, T., 1998). Some evidence suggests that lateral cap movement distorts the cilium sideways relative to the scolopale.

A major question is whether the mechanically activated ion channels are at the distal or proximal ends of the sensory dendrite. Type 2 chordotonal sensilla more closely resemble other type I arthropod sensilla, where the evidence favors distal transduction. Therefore, the primary stimulus in these sensilla is probably compression of the tube, causing stress of the dendrite membrane against the internal tubular body and opening mechanically activated ion channels in the membrane (Field, L. H. and Matheson, T., 1998). The issue is more complex for type 1 sensilla.

3.12.4.3 Ciliary Functions in Type 1 Chordotonal Sensilla

Type 1 sensilla have prominent ciliary structures with well-defined roots (Figure 1; Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). The axoneme contains nine doublet microtubules but lacks a central pair of singlet microtubules, except in some Lepidoptera. There is a dilation about two-thirds of the distance along the scolopale, where the microtubules are embedded in dense material and connected to the ciliary membrane. These structures probably play important roles in sensory transduction. Bending of the axoneme near the basal body (about the asterisk level in Figure 1) was seen, particularly during mechanical stimulation (Moran, D. T. *et al.*, 1975; Field, L. H. and Matheson, T., 1998; Yack, J. E., 2004). This was originally interpreted to mean that lateral movement of the distal dendrite produces active sliding of the axonemal microtubules, resembling a ciliary beat, distorting the neuronal membrane near the basal body, and opening mechanically activated channels located there (Moran, D. T. *et al.*, 1975).

Arguing against active axonemal beats are the lack of a central pair of microtubules, the fact that microtubules are not essential for transduction, and that transduction probably occurs at the tips of the dendrites in other type I sensilla (French, A. S., 1988). However, an active model has been revived by evidence that axonemes lacking the central pair of microtubules can be motile, that otoacoustic emissions can be recorded from some insect ears, and that mutations affecting the dynein arms of the axoneme prevent auditory transduction in *Drosophila* (Eberl, D. F., 1999; Eberl, D. F. *et al.*, 2000). These data support a model in which transduction occurs distally, but the sensitivity

of the sensillum is increased by positive feedback via axonemal movement. This could include direct connections between the microtubules and the transduction channels (Gong, Z. *et al*., 2004).

The importance of the ciliary dilation is shown by the strongly reduced receptor potentials in *Drosophila* mutants that specifically change the morphology of the dilation (Eberl, D. F. *et al*., 2000), but it is not clear if the primary role of the dilation is in transduction or in amplification. It is also possible that relatively slow, active movements of the scolopale or axoneme could adjust sensillum sensitivity to accommodate the stimulus level, providing adaptation similar to that in vertebrate ears.

3.12.4.4 Transduction and Action Potential Encoding in Chordotonal Sensilla

The scolopale lumen is assumed to provide the functional equivalent of the sensory lymph space in other type I sensilla. Morphological evidence of a sealed space supports this but no direct measurements of transepithelial potentials or concentration gradients exist (Yack, J. E., 2004).

Some of the evidence for mechanotransduction by TRP channels mentioned above was obtained in chordotonal sensilla. Several of these proteins are required for normal hearing function and are located in *Drosophila* chordotonal sensilla, but none has yet been shown to be part of the primary transduction channel (Gong, Z. *et al*., 2004).

The ionic basis of action potential encoding in chordotonal organs has not been directly demonstrated by voltage clamp experiments, but is assumed to resemble other type I sensilla. Action potential initiation probably occurs close to the mechanically activated ion channels in the distal dendrites. Evidence for this comes from extracellular recording and from observation of dendritic action potentials that sometimes fail to propagate through the soma (Hill, K. G., 1983). Firing rates in chordotonal organs show a range of adaptation behaviors (Field, L. H. and Matheson, T., 1998), which are probably controlled by voltage- and calcium-activated ion channels (DiCaprio, R. A. *et al*., 2002).

Glossary

columella The middle ear ossicle in frogs. It consists of three portions: pars externa (i.e., extracolumella), pars media, and pars interna.

diffraction Distortion of the sound field by an object, such as a head shadow.

directionality The directional sensitivity of a receiver.

directivity pattern The physical directional characteristics of a receiver.

dorsal medullary nucleus The first auditory nucleus in the frog brainstem, analogous to the cochlear nucleus in mammals.

extracolumella Pars externa of the columella. The part of the columella that attaches to the tympanic membrane.

extratympanic input Sound inputs to the ear other than that from the tympanic membrane.

interaural acoustic coupling The strength of acoustic coupling between the two ears in frogs, lizards, crocodiles, and some birds. The two ears are connected acoustically through Eustachian tubes and mouth cavity.

interaural level difference (ILD) Refers to the difference in sound pressure levels at the two ears (usually due to diffraction).

interaural time difference (ITD) Refers to the difference in time/phase at the two ears due to the disparity in the path lengths from an off-axis source.

pressure-difference receiver An acoustic receiver where tympanic membrane vibration is a product of interaction of sound arriving at both sides of the membrane.

Torus semicircularis Mid-brain auditory center, the homolog of the mammalian inferior colliculus.

3.13.1 Introduction

Most vertebrates can determine the location of a sound source by evaluating several interaural cues: interaural phase/time differences (ITD), interaural level differences (ILD), and interaural spectral differences. According to the duplex theory, localization of low- and high-frequency sounds largely depends on analysis of the ITD and ILD, respectively (Wightman, F. L. *et al.*, 1987). ITD processing is effective at low frequencies due to the facts that phase coding is prominent, and encoding of interaural phase differences is unambiguous. In contrast, ILD is most pronounced for high-frequency sounds. This is because when the head size is larger than one-quarter of the sound wavelength (as a general rule),

the head diffracts the sound and becomes an obstacle to sound propagation, thereby producing a head-shadowing effect.

For most nonmammalian vertebrates, the interaural distance is small. The sound energy of their communication signals is concentrated at low frequencies, and at the same time, hearing is generally restricted to low frequencies due to the limited high-frequency response of their middle ear bones (Manley, G. A., 1972; 1990; Mason, M. J., 2006). At low frequencies, vibration of the eardrum is transferred with little loss to the columellar footplate, but at higher frequencies energy is lost due to flexion in the extracolumella–columella link. A further limitation is that the tympanic membrane vibration tends to break up into higher vibration modes at higher frequencies (Anson, M. *et al.*, 1985; Purgue, A. P., 1997). In these modes, nodes can form at the extracolumellar attachment, effectively limiting the sound input to the inner ear to frequencies below 12 kHz in nonmammals. For most species, the auditory sensitivity drops around 5 kHz; here, the wavelength is 6.8 cm, so for the smallest animals (head size ~1 cm) the diffraction is only just measurable.

3.13.2 Sound Localization in Nonmammalian Vertebrates

Nonmammalian vertebrates can localize sound with varying degrees of accuracy. Frogs can locate a source of species' advertisement calls with an accuracy of ~20° (see reviews by Fay, R. R. and Feng, A. S., 1987; Christensen-Dalsgaard, J., 2005). Acuity of sound localization differs widely in birds, ranging from 3° to 5° in barn owls (Knudsen, E. I. *et al.*, 1979; Bala, A. D. S. *et al.*, 2003) and 2° to 8° in two hawk species (Rice, W. R., 1982), to ~25° in canaries (Klump, G. M., 2000; Christensen-Dalsgaard, J., 2005). In general, acuity of sound localization for small animals that hear low-frequency sounds is poorer than larger animals hearing higher-frequency sounds. Also, small animals must utilize special mechanical adaptations to achieve the localization acuity they possess (see Chapters 3.11, 3.35, 3.36, and 3.41).

3.13.3 Interaural Acoustic Coupling

In anurans (frogs and toads), lizards, crocodiles, and some bird species, the ears are connected acoustically through Eustachian tubes or interaural canal and mouth cavity. As a result, sound can travel relatively unobstructed from one ear to the other. Such acoustical coupling allows the direct component of sound at the external surface of the eardrum and the indirect component at the internal surface of the eardrum to interact, forming a pressure-gradient (or pressure-difference) receiver that enhances the directionality of the ear. In essence, for them, binaural interaction takes place on the tympanum itself. As to be described later, the interconnection between ears is most remarkable in the lizards, for which the eardrum directionality provides ILDs of up to 34 dB. In mammals, although the ears are also connected through the Eustachian tubes, the sound attenuation through the interaural pathways is so large that the ears act as independent pressure receivers. For them, directional information is extracted by the central nervous system by evaluating the interaural cues.

The pressure-difference receiver functions to amplify the amplitude and phase differences at the two eardrums, generating larger ITD and ILD than expected from the size of the animal. This amplification is strongly dependent on the acoustical coupling between the ears. The driving force for the eardrum vibrations is the instantaneous pressure difference between its sides, that is, $U = P_{\text{direct}} - P_{\text{indirect}}$. The indirect component is phase shifted and attenuated relative to the direct component when it reaches the internal side of the eardrum. For a sinusoidal sound, the expression becomes $U = \sin(\omega t) - B\sin(\omega t + \Delta\phi)$, where B is the amplitude ratio between direct and indirect sound, $\Delta\phi$ is thephase difference between direct and indirect sound, and ω is the frequency. It is useful to rewrite this expression as

$$U = \sqrt{1 + B^2 - 2B\cos\Delta\phi} \times \sin\left(\omega t + \arctan\left(\frac{-B\sin\Delta\phi}{1 - B\cos\Delta\phi}\right)\right) \quad [1]$$

The expression shows that the driving force strongly depends on the amplitude ratio B, that is, on the interaural attenuation, and on the phase shift between direct and indirect sound. The amplitude varies between $1 + B$ and $1 - B$, depending on the phase difference; for B with a value greater than zero the amplitude will be greater than the original signal at some phase differences. Note that for $B >> 1$ the phase shift of the difference signal approaches $\Delta\phi$, that is, the phase difference of the indirect sound. The operation thus results in larger interaural level and time differences compared to the cues generated by diffraction. Additionally, the greater ILD amplifies the ITD

further in light of the differential latency shifts of VIII nerve fibers on both sides (Feng, A. S., 1982).

The pressure-difference receiver ear is presumably the ancestral condition of the tetrapod tympanic ear, since the first eardrums were compliant, skin-covered fenestrations in the skull contacted by the middle ear ossicle and therefore coupled through the mouth cavity (Clack, J. A., 1997; Christensen-Dalsgaard, J., 2005). This configuration is similar to that found in present-day anurans and lizards, whereas the pressure-sensitive ear of mammals and some birds represent the derived condition of shielding the tympanum and ossicle in the middle ear cavity. The increasing isolation of the middle ear cavities may have evolved initially for isolating the ear from the respiratory and food-intake pathways (Christensen-Dalsgaard, J. and Manley, G. A., 2005a).

3.13.3.1 Anurans and Lizards

As shown above, pressure-difference receiver characteristics depend on the acoustical coupling between the ears. For frogs and lizards whose eardrums are acoustically coupled, the indirect component is non-negligible and frequency dependent. As such, frog and lizard ears behave like a combination pressure and pressure-difference receiver (Fay, R. R. and Feng, A. S., 1987). The directivity index V for such a receiver (consisting of a membrane, a cavity, and a second sound entry via the opposite membrane) is a function of the incident angle θ (Beranek, L. L., 1986) and can be modeled by

$$V = 20\log\frac{1 + B\cos\theta}{1 + B} \quad \text{where } B = \frac{\Delta L}{c\,C_A R_A}$$

B is a dimensionless constant with a value ranging from 0 to infinity, ΔL is the distance between the eardrums, c the speed of sound, C_A the acoustic compliance, and R_A the acoustic resistance of the cavity. If ears are uncoupled (i.e., thus having a large interaural resistance), B approaches zero; each ear then functions as a pure pressure receiver and is omnidirectional. Conversely, if the ears are tightly coupled (i.e., having a small interaural resistance or a very large B), the directivity will approach $V = 20\log\cos\theta$. This condition approximates a pure pressure-difference receiver and confers a figure 8 directionality with a prominent null for sound coming from the frontal and caudal directions. The acoustic receiver of frogs and lizards has moderate B values, showing frequency-dependent directional responses and giving rise to ILD that is greater than can be expected from the size of the animal.

More complicated models that also include the acoustical properties of the eardrums and of the Eustachian tubes can be made from electrical network analogs (Fletcher, N. and Thwaites, S., 1979; Fletcher, N. H., 1992). Briefly, any acoustical system where acoustical flow is one dimensional (e.g., propagation in tubes and through membranes) with all elements smaller than one half wavelength will have an analogous electrical circuit where cavities correspond to capacitors, tubes to inductances (at low frequencies; for high-frequency approximations, see Fletcher, N. H., 1992), and sound absorbers to resistances. See also Lewis E. R. (2004) for an introduction to modeling. Electrical network analogs have been used in modeling the acoustics of the frog and lizard ear (see below).

The external and middle ears of frogs and lizards share some similarities, even though their tympanic ears probably originated independently in the two groups (Clack, J. A., 1997). In both groups, the Eustachian tubes are wide and short with a considerable acoustical coupling between the two ears. Both frogs (see Lewis, E. R. and Narins, P. M., 1999 for general review of the auditory periphery) and lizards have a single middle ear ossicle connected to the eardrum via a cartilaginous extracolumella; flexion in the extracolumella–columella link limits the high-frequency sensitivity of the lizard ear (Manley, G. A., 1972; 1990) and probably also that of the anuran ear (Mason, M. J., 2006). However, there are notable differences between the directionality of frog and lizard ears (see Christensen-Dalsgaard, J., 2005). Frog ears generally show directional differences of up to 10 dB within a relatively narrow directional band (500 Hz), whereas lizards show directional differences of up to 34 dB and a wider directional bandwidth (>2 kHz; Christensen-Dalsgaard, J. and Manley, G. A., 2005a).

3.13.3.1.1 Anurans

Figure 1 shows the directionality of the eardrum of a treefrog *Eleutherodactylus coqui*, measured by laser vibrometry. The eardrum directionality is poor at low and high frequencies; maximum directionality is observed at ~1.7 kHz, having an ovoidal directional characteristic with the largest response from ipsilateral angles (Jørgensen, M. B., 1991; Jørgensen, M. B. *et al.*, 1991). The acoustics of the frog periphery are complicated, mainly due to its multiple acoustic

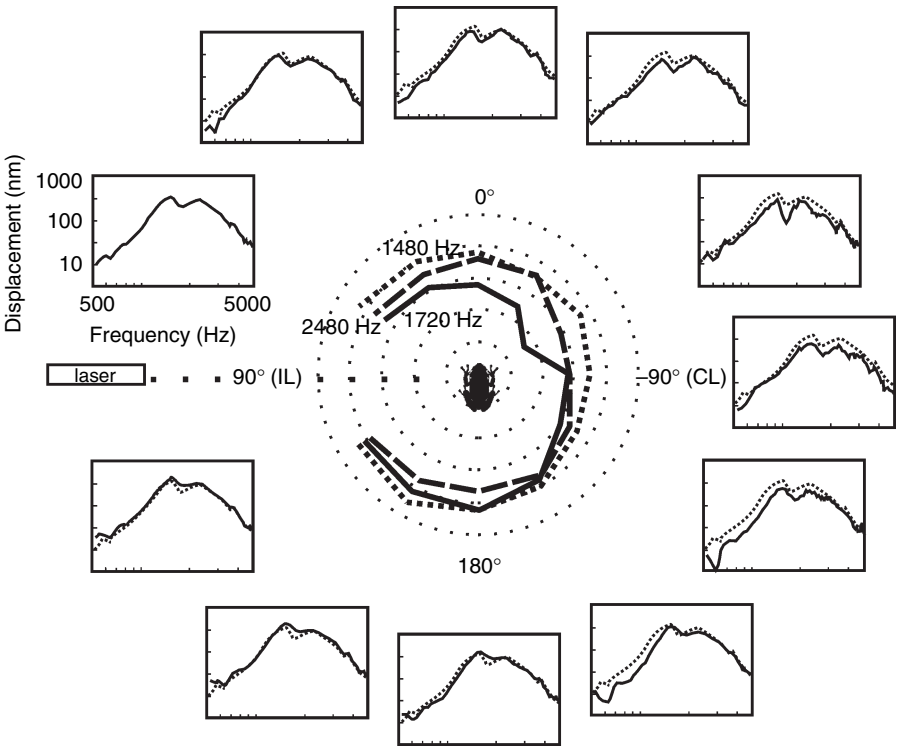

Figure 1 Directional response of the eardrum in *Eleutherodactylus coqui* measured by laser vibrometry. The figure shows polar plots at three frequencies, and the inset figures are vibration spectra taken at different directions. In each figure, the ipsilateral (IL) spectrum is shown as a reference (thin line). Reprinted from Jørgensen, M. B., Schmitz, B., and Christensen-Dalsgaard, J. 1991. Biophysics of directional hearing in the frog *Eleutherodactylus coqui*. J. Comp. Physiol. A 168, 223–232 and Christensen-Dalsgaard, J. 2005. Directional Hearing in Non-Mammalian Tetrapods. In: Sound Source Localization (*eds*. A. N. Popper and R. R. Fay), pp. 67–123. Springer, with kind permission of Springer-Verlag.

inputs. Sound is transmitted through not only the coupled eardrums, but the lungs are also efficient inputs for low-frequency sound (Narins, P. M. *et al.* 1988; Jørgensen, M. B. *et al.*, 1991). Also, the mouth cavity may be transparent to sound, and finally, there is an extratympanic low-frequency input (Feng, A. S. and Shofner, W. P., 1981; Wilczynski, W. *et al.* 1987; Wang, J. *et al.* 1996) that can be inferred from VIII nerve recordings. In response to low-frequency free-field sound (100–400 Hz), VIII nerve auditory fibers show a strong figure 8 directionality with a frontal null (Figure 2(a)), that is, decreased responses at frontal angles (Feng, A. S., 1980; Jørgensen, M. B., 1991; Jørgensen, M. B. and Christensen-Dalsgaard, J., 1997b), in spite of the fact that the tympanum is insensitive to sounds at such low frequencies and shows no directional characteristic. As shown in Figure 2(b), at higher frequencies, the directional characteristic of the auditory fibers is ovoidal and matches the directionality of the eardrum (Feng, A. S., 1980; Jørgensen, M. B. and Christensen-Dalsgaard, J., 1997a).

In *Rana pipiens* it was shown that the ear directionality as measured by the directional responses of primary auditory nerve fibers are altered when the interaural transmission is manipulated (Feng, A. F. and Shofner, W. P., 1981). Reducing the interaural transmission by filling the mouth cavity with moist cotton decreases the ear directionality at all frequencies; the ovoidal directivity pattern at high frequencies becomes omnidirectional and the figure 8 directivity pattern at low frequencies becomes ovoidal (second row of Figure 3). In contrast, coating the contralateral eardrum with rubber cement (which attenuates the sound through this ear) leaves the directionality and directivity pattern at low frequencies unchanged; the directionality of mid- and high-frequency fibers is reduced, and the directivity pattern becomes omnidirectional (third row of Figure 3), indicating that the tympanum is the source of the ear directionality at mid- and high frequencies. Finally, opening of the frog's mouth cavity that facilitates interaural transmission produces an increase in the

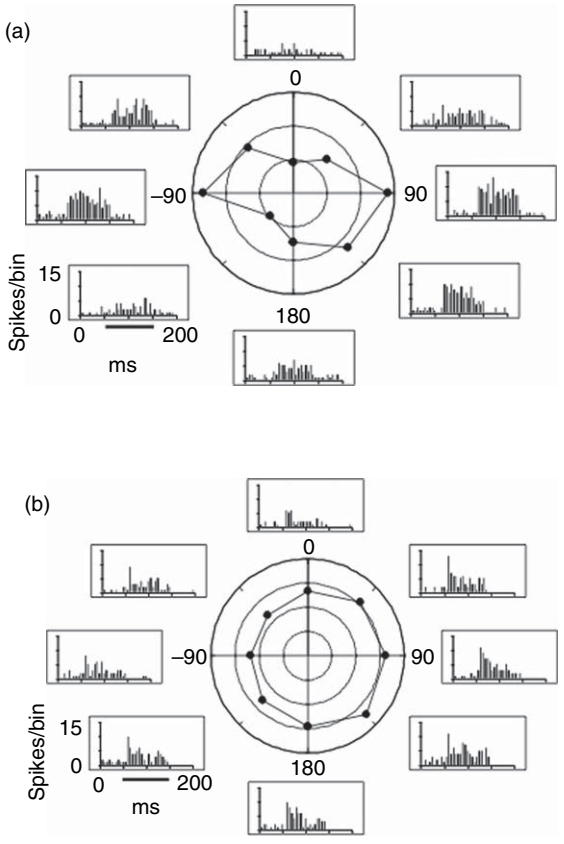

Figure 2 Directional responses of VIII nerve fibers in *Rana temporaria*. (a) Is the response of a low-frequency fiber stimulated at its best-frequency (BF) (300 Hz). Note the figure 8 response with low sensitivity at frontal directions. (b) Shows ovoidal response of a high-frequency fiber stimulated at its BF (1500 Hz). Reprinted from Jørgensen, M.B. and Christensen-Dalsgaard, J. 1997a. Directionality of auditory nerve fiber responses to pure tone stimuli in the grassfrog, *Rana temporaria*. I. Spike rate responses. J. Comp. Physiol. A 180, 493–502, with kind permission of Springer-Verlag.

ear directionality (suggesting that the mouth floor is not transparent to sound) and converts the directivity pattern at all frequencies into a figure 8 pattern (bottom row of Figure 3). These experiments are consistent with the results of mechanical measurements showing that the ear directionality at low frequencies is due mainly to the extratympanic route, whereas directionality at higher frequencies is produced by the acoustics of the coupled middle ear cavities and respiratory pathway, and that the frog's ear functions as a combination pressure–pressure difference receiver.

The source of the extratympanic input is unclear. Jørgensen M. B. and Christensen-Dalsgaard J. (1997b) suggested that sound-induced vibrations of the frog's skull likely produce movements of the inner-ear fluids that would have maximal amplitude in certain directions. However, since detympanation also affects the sensitivity and directionality at low frequencies (for which the source is extratympanic; Christensen-Dalsgaard, J. *et al.*, 1997), the tympanic and extratympanic pathways must be closely coupled, and the directionality is likely a product of interaction of these two pathways.

3.13.3.1.2 Lizards

In all lizards investigated, the middle ears are connected by large cavities in the upper palate. Thus, the lizard head is acoustically transparent, with an interaural attenuation of close to zero over a broad frequency range and thus large directionality of eardrum vibration (Figures 4(a) and 4(b), Christensen-Dalsgaard, J. and Manley, G. A., 2005b). The directional response is asymmetrical with a large gradient along the frontal directions (Christensen-Dalsgaard, J. and Manley, G. A., 2005a; 2005b). The directionality is abolished when one eardrum is occluded. A simple acoustical model having two tympanic inputs and a central cavity accurately describes the directionality of this ear (Figures 4(c) and 4(d)). By comparison, models of the directionality of the anuran ear do not fit the measured physiological responses, neither can they predict an increased directionality at low frequencies, a reduced directionality around the frequencies of maximal sensitivity (Aertsen, A. M. H. J. *et al.*, 1986), or a figure 8 response at low frequencies (Palmer, A. R. and Pinder, A. C., 1984). The discrepancy between model predictions and experimental data probably is due to the complicated acoustics of the frog periphery. For example, the lung input was not known at the time these models were made. Moreover, since the lung input covers most of the dorsum of the frog it is difficult to approximate by a single point input.

3.13.3.2 Avians

The ears of avians and crocodilians are similarly connected by an interaural canal. The functional significance of this connection varies among species and depends on the interaural attenuation (see reviews by Klump, G. M., 2000; Christensen-Dalsgaard, J., 2005). In the barn owl, for example, the interaural attenuation increases from 13 dB at 3.5 kHz to 63 dB at 7 kHz; at the behaviorally important high frequencies the ears are, therefore, functionally isolated (Moiseff, A. and Konishi, M.,

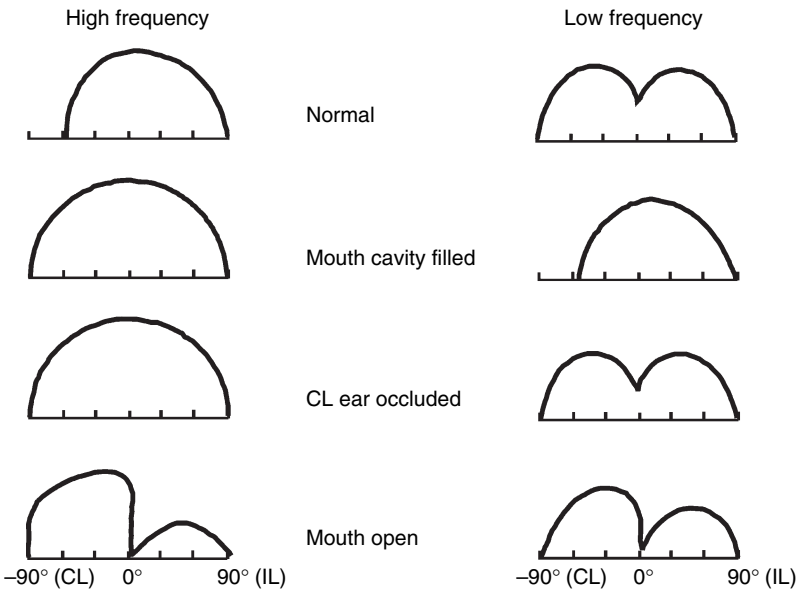

Figure 3 Directivity patterns of the frog's ear at low and high frequencies under several different experimental conditions. Top row shows directivity patterns from intact frogs. Second row shows directivity patterns from frogs whose mouth cavity was filled with moist cotton. Third row shows directivity patterns from frogs whose contralateral (CL) ear was occluded by coating with rubber cement. Fourth row shows directivity patterns from frogs whose mouth was artificially open during the recording session. IL, ipsilateral. Reprinted from Feng, A. S. and Shofner, W. P. 1981. Peripheral basis of sound localization in anurans. Acoustic properties of the frog's ear. Hear. Res. 5, 201–216, with kind permission of Elsevier B.V.

1981). In contrast, in quail (*Coturnix coturnix*), interaural attenuation is less than 5 dB at frequencies below 5 kHz; consequently the directivity patterns are cardioid at low frequencies and figure 8 at high frequencies with up to 10–20 dB directional differences (Hill, K. G. *et al.*, 1980). Similar directional characteristics have been reported for all other bird species that have prominent interaural canals.

Larsen O. N. *et al.* (1997) showed that the interaural coupling and normal operation of the tympanum of budgerigars is dependent on the intracranial air pressure, and that such pressure tends to decrease in anesthetized birds unless the middle ear cavity is vented. The result is that tympanic vibrations are impeded (with the tympanum sucked inwards), the interaural coupling is reduced by ~20 dB, and the tympanal directivity is at least 6 dB less in nonvented compared to vented birds.

Calford M. B. (1988) has modeled the bird's auditory receiver. The model calculates the pressure difference at the tympanum by adding the direct and indirect sound, delayed by travel time around the head and through the interaural canal. The model reveals the effects of interaural attenuation on the directional response and allows calculation of phase changes associated with the pressure-difference receiver. However, a drawback is that the attenuations and phase changes in the model are not frequency dependent.

3.13.4 Concluding Remarks

The interconnected ears are a primitive feature of the tetrapod tympanic ears and have been exploited for enhancing sound localization ability through fine-tuning of the acoustical elements. An inherent drawback of the pressure-difference receiver ear produced by the acoustical coupling is the strong frequency dependence of the directionality (notably in lizards and anurans) and the sensitivity to noise generated by respiration. Selection pressures associated with the need to localize high-frequency sounds probably have led to specialized, functionally isolated ears in some species of birds, most notably the barn owl. Because of the frequency dependence of directionality, central binaural processing may be different in animals having interconnected ears versus animals with isolated pressure receivers. As of to date, there is no clear evidence for separation of time and

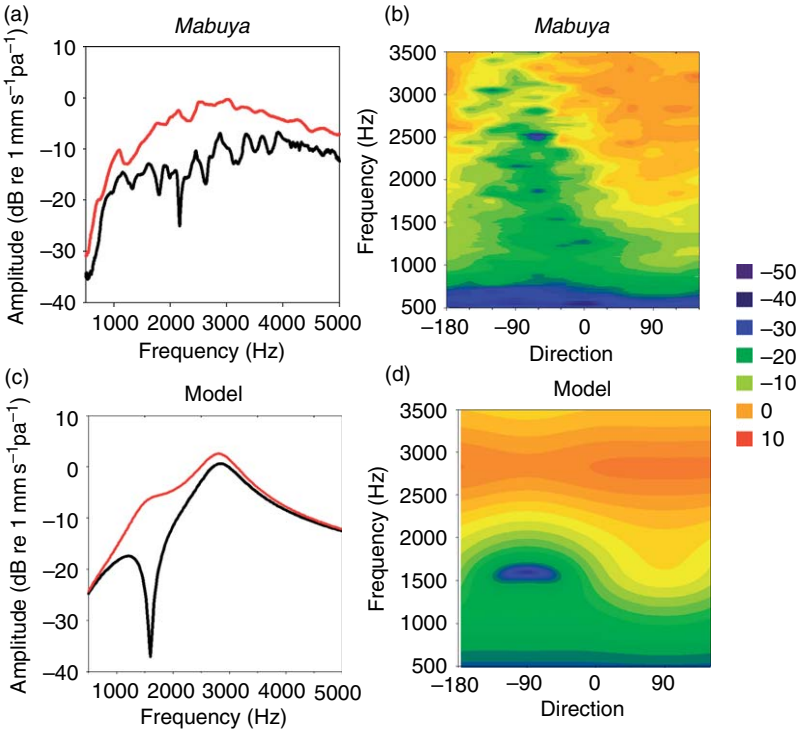

Figure 4 Eardrum vibrations in a lizard (*Mabuya macularia*) stimulated with directional sound (a, b). For comparison, data from a model based on physical parameters from Mabuya is shown in the lower row (c, d). In panels (a) and (c), ipsilateral and contralateral spectra are shown in red and black, respectively. Contour plots in (b) and (d) show the vibration amplitude (color scale, in dB re 1 mm s^{-1} pa^{-1}) as a function of direction (positive angles are ipsilateral sound directions) and frequency. Each horizontal line corresponds to a polar plot. Redrawn from Christensen-Dalsgaard, J. and Manley, G. A. 2005a. Directionality of the lizard ear. J. Exp. Biol. 208, 1209–1217, with kind permission of The Company of Biologists.

intensity processing pathways in frogs, as reported for the barn owl and mammals (Carr, C. and Code, R. A., 2000), and the existence of spatial maps also remains elusive. Instead, the available evidence suggests that central directional processing at the level of the dorsal medullary nucleus (Feng, A. S. and Capranica, R. R., 1976; Christensen-Dalsgaard, J. and Kanneworff, M., 2005) and torus semicircularis (Feng, A. S., 1981; Zhang, H. *et al.*, 1999) sharpens the peripheral directionality – this seems sufficient for providing the frog with ability to steer toward the direction of a sound source.

Glossary

audiogram A graph of hearing ability conventionally displayed as frequency in hertz or kilohertz (abscissa) versus sensitivity expressed as sound pressure level or intensity measured in decibels (ordinate).

bony fishes All fishes with skeletons made of bone. This is the largest of all vertebrate groups and includes most of the species commonly thought of as fishes such as goldfish, tuna, etc.

cartilaginous fishes Sharks, skates, and rays. The skeleton in these species is made of very dense cartilage rather than bone.

Cetacea The name of the taxonomic order encompassing all whales, dolphins, and porpoises derived from the Latin word for whale, *cetus*. There are two suborders: Mysticeti (baleen whales) and Odontoceti (toothed whales) (see below).

cochlea The snail-shaped canals and sensory organs of the inner ear that provide hearing by transforming sound energy into neural impulses.

decibel (dB) A unit of measurement based upon the logarithm of the ratio of pressure versus an arbitrary reference pressure. For sound measurements, the decibel scale usually represents sound pressure level (SPL), but it may also be used as a measure of intensity (pressure squared). The reference pressures used are different for air (20 μPa) and underwater (1 μPa) sound measurements; therefore, the decibel level of a sound is properly stated in the form of *n* dB re *n* μPa. Two sounds that are perceived as equally loud may have different decibel values based on the reference pressures used in the measurements. Two sounds with equal intensity would have a 100 dB re 20 μPa in air but a decibel value in water of approximately 160 dB re 1 μPa.

echolocation The ability to image features of the environment including size, shape, and location of an object by analyzing echoes from a self-generated sound. Bats and toothed whales have the best known animal echolocation or biosonar.

end organ The sensory regions of the inner ear, particularly the otolithic receptors and the receptors of the semicircular canals.

hertz A unit of sound frequency equal to 1 cycle s^{-1} (see also kHz).

impedance A complex ratio of power versus flow properties, describing effectively the resistance or efficiency of transfer. Acoustic impedance can be thought of as the impact of the medium on sound transmission.

inner ear The combined organs of hearing and balance, the cochlea and vestibular system.

infrasonic Frequencies below 20 Hz, the lower extreme of human hearing.

kilohertz (kHz) Equals 1000 Hz (or 1000 cycles s^{-1}).

lagena One of the end organs of the ear in fishes. It is also present in all nonmammalian terrestrial vertebrates.

lamprey A group of primitive vertebrates that do not have a lower jaw. Lampreys represent the most primitive group of vertebrates.

mandible Lower jaw bone.

masking The impact of one sound on the ability to detect another sound.

middle ear The chamber and structures that amplify sound and connect the outer ear and inner ear. A form of middle ear is found in all terrestrial vertebrates.

Mysticetis The suborder of baleen-bearing or moustached whales comprising all great whales such as blue, finback, right, and humpback whales. Baleen is a series of horny overlapping plates with feathered edges that mysticetes use in lieu of teeth for straining food. Mysticetes have not been shown to echolocate.

octave An octave is broadly defined as a doubling of frequency. Thus, a one octave shift from 500 Hz is 1000 Hz; from 3000 Hz it is 6000 Hz. Adult humans have on typically an eight-octave functional hearing range of 32 Hz to 16 kHz.

octavolateralis system The term that refers to the combined ear and lateral line system of fishes.

Odontoceti The suborder of cetaceans comprising the toothed whales, such as sperm whales, dolphins, and porpoises. All odontocetes are believed to echolocate (to use sound for imaging the environment).

ossicles The bones that act as levers in the middle ear to amplify and transduce sound energy impinging on the tympanum or eardrum into mechanical forces driving the inner ear responses.

otoconia Calcium carbonate crystals found in the otolithic organs of terrestrial vertebrates, cartilaginous fishes, and primitive bony fishes. The crystals are embedded in a gelatinous matrix.

otolith Calcium carbonate structures found in the saccule, lagena, and utricle of most bony fishes. The otolith is several times denser than the rest of the fish body. Relative motion between the otolith and the sensory epithelium results in stimulation of the sensory hair cells. The saccular otolith has growth rings that can be visualized to determine fish age.

otolithic organs A general term for the saccule, lagena, and utricle of the inner ear. Each has a sensory epithelium and an overlying calcium carbonate mass (otoconia or otolith, depending on the species). Relative motion between the mass and the sensory epithelium causes excitation of the sensory hair cells.

Otophysi A group of fishes that includes goldfish, catfish, and carp. All members of this mostly freshwater group of fishes have a series of bones, the Weberian ossicles, which connect the swim bladder to the inner ear.

pinna The outer ear flap in most mammals, including humans. The pinnae assist with focusing sound and localization, the ability to detect the direction of a sound.

Pinnipedia The marine mammal order comprised of seals, sea lions, and walruses.

rorquals A type of baleen whale that feeds on small fish and zooplankton by lunge-feeding.

saccule One of the regions of the ear. In fishes the saccule is generally considered to be the major auditory end organ but it may also be used to determine head position relative to gravity. In terrestrial vertebrates and all mammals, the saccule, along with the utricle, provides information about head position relative to gravity and helps the animal maintain eye position as head position changes.

semicircular canals Fluid filled canals of the restibular system of the inner ear. Motion of these fluids excite cells that detect angular acceleration of the head. Feedback from the canals affects eye movements.

sensory hair cells The fundamental cell of the inner ear and lateral line of vertebrates. These cells detect mechanical motion and convert that motion to a signal that can stimulate the nerves that carry information to the brain.

sound localization Determination of the position of a sound source compared to the position of an animal based on differences in its intensity and arrival times between ears or receptors.

swim bladder An air chamber in the abdominal cavity of most bony fishes that is used to adjust buoyancy so that the animal can maintain its position in the water column without expenditure of energy. The swim bladder in some fishes is used in sound production and in sound detection.

ultrasonic Sounds above 20 kHz, which is the upper extreme of human hearing.

utricle One of the regions of the inner ear. In fishes the utricle is involved in both hearing and determination of head position relative to gravity. In terrestrial vertebrates and all mammals, the utricle is primarily a receptor for determination of head position relative to gravity and helps the animal maintain eye position as the head changes position.

vestibular system The part of the inner ear, that determines the position and acceleration of the head relative to gravity, commonly thought of as the balance system. The vestibular system includes the

sensory organs of the saccule and utricule plus the semicircular canals.

Weberian ossicles A series of bones between the swim bladder and inner ear of Otophysan fishes that appears to enhance hearing by serving as an acoustic coupling device between the pressure-receiving swim bladder and the saccule of the inner ear in a way that is functionally analogous to the middle ear of terrestrial vertebrates.

3.14.1 The Origins of Vertebrate Underwater Hearing

The vertebrate ear and hearing evolved in aquatic animals. Although there is no evidence as to when the first vertebrates were able to hear, it is likely this occurred several hundred million years ago.

Once vertebrates came onto land, they had to develop an array of new mechanisms to enable use of their fluid-filled and water-adapted inner ears for detection of airborne sounds. The problem that terrestrial vertebrates had to overcome was the difference in impedance between the fluids of the inner ear that had evolved to detect sound in water and the impedance of sound in air. Without special structures for capture, transduction, and amplification, the sound energy in air would not be efficiently transferred to the fluids of the inner ear. As a consequence, airborne sound would be largely undetectable. This need to accommodate the impedance mismatch of air and water led to the evolution of the middle ear present in virtually all terrestrial vertebrates.

Conversely, there was also a readaptation when air-adapted vertebrates once again entered the water. Air-adapted ears of land animals (including human divers) function poorly in water because they are not adapted to the higher pressures and faster sound speeds in water (approximately $1550\,m\,s^{-1}$ in water versus $330\,m\,s^{-1}$ in air) that are critical elements for discriminating between sounds and determining the position of a sound source in the space. Consequently, aquatic vertebrates have two levels of adaptation: the original water-derived ear of fishes and a range of partial to full remodifications of an air-to-water ear in animals that have returned to the marine environment.

3.14.2 The Evolution of Vertebrate Hearing in Water

The earliest vertebrates were jawless species resembling the modern-day lamprey. Lampreys, like their vertebrate ancestors, have a very recognizable ear with sensory cells and other structures similar to those of modern vertebrates. However, because the ear comprises both the vestibular and auditory senses, it is not clear whether the earliest ears were primarily for hearing or for detecting acceleration and head position.

Even if ears did not originally arise for hearing, they likely subsumed this role very early in the evolution of vertebrates because there were considerable selective pressures favoring sound detection (van Bergeijk, W. A., 1967; Wever, E. G., 1974; Fay, R. R. and Popper, A. N., 2000). In effect, hearing is likely to have arisen because other senses available to the earliest vertebrates, including vision, touch, and olfaction, function effectively only over short ranges. For example, vision can only function when there is sufficient light to excite photoreceptors in the eye (Fay, R. R. and Popper, A. N., 2000) and light does not penetrate very far into the ocean. In contrast to light, sound travels well in water, and the ocean is filled with sounds (Wenz, G. M., 1964) that can provide animals, through hearing, with a broader range of information about the environment at greater distances from the receiver than virtually any other sense.

Animals just detect presence of sound to use it effectively. Particularly for survival, the animal needs to be able to determine the direction and, ideally, the relative distance of sounds and to determine which are biologically relevant (e.g., predator, prey, mate, or competitor) in the presence of other sounds. Thus, it is possible to hypothesize that very early in the evolution of hearing, vertebrates developed mechanisms that would enabled them to localize sound sources, discriminate among signals, and detect signals in the presence of masking noise. This implies that in addition to evolving an ear, they also had to evolve the mechanisms for analyzing multiple features of sounds (e.g., Fay, R. R. and Popper, A. N., 2000).

It is likely also that use of sound for communication among animals of the same species, such as for mating, evolved later than hearing per se. Although data are limited, it is known that sharks and rays use sound to detect possible prey, but there is no evidence that any member of this very successful

vertebrate group uses sound for communication (Myrberg, A. A., 2001). Similarly, although goldfish have excellent hearing (Fay, R. R., 1988), no one has yet detected that goldfish producing sounds. Marine mammals by contrast employ complex signals not only for communication but, in some cases, for sophisticated acoustic imaging called echolocation or biosonar as discussed below.

3.14.3 The Inner Ear of Fishes

The ears of cartilaginous fishes (sharks and rays) and of bony fishes resemble those of terrestrial vertebrates (Figure 1). All vertebrate ears (other than jawless fishes) have three semicircular canals that are used for determination of angular acceleration. They also have several otolithic end organs, two of which, the saccule and utricle, are found in all vertebrates. The third end organ, the lagena, is found in all vertebrates except mammals but may have given rise to the cochlea (Wever, E. G., 1974). The function of the otolithic end organs in terrestrial animals is to determine head motion relative to gravity. For fishes, however, these organs provide vestibular functions as well as hearing (Platt, C., 1983; Popper, A. N. *et al.*, 2003).

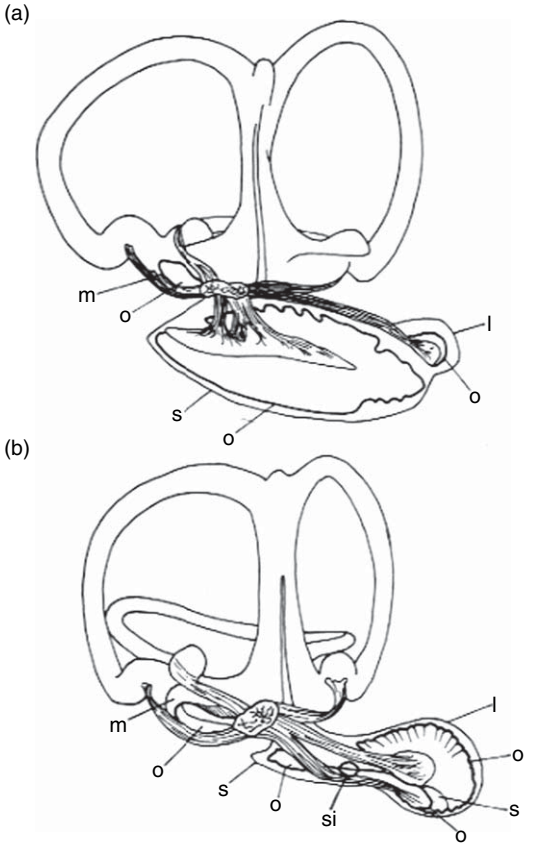

Figure 1 Illustrations of the right inner ears from the perch *Stizostedion lucioperca* (formerly *Lucioperca sandra*) (a) and goldfish *Carassius auratus* (b). Both from Retzius G. (1881). l, lagena; m, utricular macula; o, otolith; s, saccule; si, sinus impar (to connect left and right ears in goldfish). Anterior is to the left and dorsal to the top.

Fish hearing involves the use of sensory hair cells that are virtually the same as those found in terrestrial vertebrates (Coffin, A. *et al.*, 2004). In cartilaginous fishes (sharks and rays), terrestrial vertebrates, and more primitive bony fishes (e.g., sturgeon and lungfish), the sensory epithelium containing the sensory cells is overlain by a mass of calcium carbonate crystals (otoconia) embedded in a gelatinous matrix. In the majority of bony fishes, however, the calcium carbonate fuses into a single dense structure, the otolith. Hearing by fishes results when a sound field impinges on the body and moves tissues more readily than the denser otoliths. Because the ciliary bundles on the hair cells are mechanically coupled to the otoliths, the relative motion between the fish's body and the otolith results in bending of the ciliary bundles and stimulation of the hair cells, leading to detection of sound (or body motion in water).

The precise role of each of the end organs in fish hearing is not known, and it is likely that the specific roles vary among the more then 25 000 extant species of fish (Popper, A. N. *et al.*, 2003). For example, the saccule is thought to be the major auditory end organ in goldfish and related species (e.g., most catfish), whereas in a few species the utricle has a major role in hearing, as discussed below.

3.14.4 Hearing Capabilities of Fishes

Hearing has been measured in cartilaginous and bony fishes. These measures include both the range of frequencies detectable and the lowest sound levels that are detected at each frequency. While limited, these data show that cartilaginous fishes are able to detect sounds up to about 1000 Hz (Figure 2). Although there are hearing data on fewer than 100 of the 25 000 species of bony fish, it is clear that there is greater variation in the abilities of bony fish to detect in sound (Figure 2). Some fishes detect sounds only up to 500–1000 Hz, whereas others can detect sounds with better sensitivity and at frequencies up to 3000 or 4000 Hz. A few species are able to detect

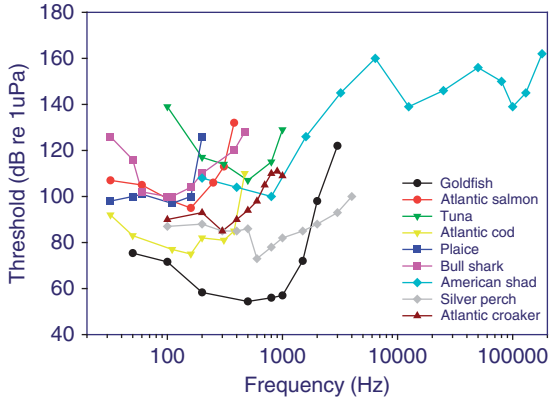

Figure 2 Auditory thresholds for a variety of different fish and shark species. Note that the audiograms were all determined using different methods. Moreover, while thresholds are most likely correctly represented using pressure values for hearing specialists such as goldfish and silver perch, it is not clear whether pressure or particle motion (not shown here) would be more suitable for the nonspecialists. All data from Fay, R. R. (1988) other than silver perch (Ramcharitar, J. U. *et al*., 2004) and Atlantic croaker (Ramcharitar, J. U. and Popper, A. N., 2004).

sounds well into the infrasonic and ultrasonic ranges (reviewed in Popper, A. N. *et al*., 2003; Ladich, F. and Popper, A. N., 2004).

Fishes that detect sounds above about 1500 Hz are often referred to as hearing specialists, whereas those that do not possess such capabilities are called nonspecialists (or generalists). It has been suggested that in the hearing specialists, one or more of the otolith organs may respond to sound pressure as well as to acoustic particle motion (e.g., Popper, A. N. *et al*., 2003). The response to sound pressure is thought to be mediated by mechanical coupling between the swim bladder (a gas-filled chamber in the abdominal cavity that enables a fish to maintain neutral buoyancy) or other gas bubbles and the inner ear. With this coupling, the expansion and contraction of the gas-filled structure in a pressure field is translated to the ear. In nonspecialists, however, the lack of a swim bladder or its lack of coupling to the ear probably results in any signal from the swim bladder attenuating before it gets to the ear. As a consequence, these fishes detect little or no pressure component of the sound (Popper, A. N. *et al*., 2003). Hearing generalists are most sensitive to sounds produced by relatively near sources.

While some hearing specialists, such as catfish, use sound for communication (as do some hearing generalists), others do not. Then here has been some question about why fishes that do not use sound for communication evolved the ability to detect higher frequencies. The most likely reason, at least for freshwater species, is that the fish evolved in shallow water where there is substantial and rapid attenuation of low frequencies (Rogers, P. H. and Cox, M., 1988). In order for these species to glean any information about their environment using sound, they would need adaptations to detect the higher frequencies that propagate over longer distances in such waters.

Specializations for enhancement of hearing generally involve mechanisms that acoustically couple an air bubble, such as the swim bladder, with the ear. It is likely that the swim bladder evolved to enable fishes to maintain neutral buoyancy, thus cutting down on energy used to maintain a particular depth in the water column. However, mechanisms have evolved that enable many fish species to use this organ for both sound production (Zelick, R. *et al*., 1999) and hearing (Ladich, F. and Popper, A. N., 2004).

The nature of the coupling between the swim bladder and inner ear varies among hearing specialists. The best-known coupling is found in the fishes of the superorder Otophysi, a group of primarily freshwater fishes that includes goldfish and catfish. These species have a series of bones, the Weberian ossicles, connecting the swim bladder directly to the inner ear. It has been hypothesized that motion of the walls of the swim bladder during sound stimulation results in motion of the Weberian ossicles that, in turn, moves the fluids of the inner ear (Alexander, R. McN., 1962) in a manner analogous to the function of the mammalian middle ear bones.

Beyond the Otophysi, there are diverse connections between the swim bladder or other air bubbles and the inner ear among taxonomically distinct species. These may include anterior projections of the swim bladder that terminate in contact with the ear and/or newly evolved air bubbles located near the ear.

One significant point about all of these structures is that multiple mechanisms evolved to enhance hearing that are spread throughout the fish taxa. Indeed, there are instances of closely related species with very different hearing capabilities and air bubble connections to the ear. For example, one species of the squirrel fish family (Holocentridae) only detects sounds to about 1000 Hz, whereas another species that lives in the same caves detects sounds to over 3000 Hz (Coombs, S. and Popper, A. N., 1979). The two species have substantial differences in ear structure and in the relationship between the swim bladder and ear.

Fishes of the commercially important family Sciaenidae (croakers and drums) also have great diversity in ear structure, in the relationship between the ear and swim bladder, and in hearing capabilities (Ramcharitar, J. U. *et al.*, 2001).

Although the saccule and lagena are most often implicated in fish hearing, there are a number of cases in which the utricle appears to have taken on a special role to enhance detection of low- or high-frequency sounds. There is evidence that some marine catfish use low-frequency echolocation to glean information about their environment (Tavolga, W. N., 1976), much as dolphins use high-frequency sounds for biosonar. Echolocating catfish have hypertrophied utricles that are hypothesized to function like a low-frequency accelerometer to detect echoes of their own sounds in order to navigate through the environment (Popper, A. N. and Tavolga, W. N., 1981).

At the other end of the frequency range, the clupeiform fishes (e.g., herring, anchovies, and sardines) have utricles unlike those found in any other vertebrate. Recent evidence has implicated this specialization for the detection of sounds up to 180 kHz in a number of clupeids including the American shad (Mann, D. A. *et al.*, 2001). The adaptive significance of this capability appears to be for the detection of sounds produced by the echolocating dolphins (Plachta, D. T. T. and Popper, A. N., 2003) that often prey upon schools of clupeids.

The bottom line is perhaps the exceptional diversity of structures that fishes have evolved that enable them to use sound to obtain environmental information. Although we are at the earliest stages of understanding this diversity, an example of the critical use of sound includes evidence that deep-sea fishes evolved specializations to enhance hearing at depths where there is little or no light (e.g., Buran, B. N. *et al.*, 2005). More recently, it has become apparent that some larval fishes use sounds produced by reefs to find places to settle (Simpson, S. D. *et al.*, 2005). Data is currently available on only a few extant species. It is likely that further study will continue to demonstrate that hearing not only evolved underwater but also that the broadest adaptations are in this environment as well.

3.14.5 Marine Mammals

Marine mammals, like fishes, encompass diverse groups of species, although it is arguable that they are less diverse than fishes. Marine mammals comprise five vertebrate groups. The two best known are the cetaceans (dolphins and whales) and the pinnipeds (seals, sea lions, and walruses). These will form the focus of this discussion because there are sufficient data on hearing in some of their component species to provide insights into how aquatic ears re-evolved from air-adapted ancestors. They also include species that range from totally aquatic to amphibious to primarily land (or ice), air-adapted ears.

Cetaceans are divided into two distinct groups. The Odontoceti (or toothed whales) are predatory high-frequency echolocators typified by the well-studied bottlenose dolphins. The Mysticeti (or baleen whales) include the largest species ever recorded, the blue whale, as well as some smaller rorqual whale species. All cetaceans live entirely in water and may spend as much as 80% of their time submerged. Pinnipeds, by contrast, are truly amphibious and all species spend some portion of their time and do key activities (e.g., breeding and rearing young) on land. The sirenians (manatees and dugongs) are, like cetaceans, obligate aquatics, but to date few manatees have been studied and there are no hearing data on dugongs. There are no hearing or ear data on any member of the two remaining and most recently evolved marine mammal groups, the sea otters and polar bears.

3.14.5.1 Marine Mammal Auditory Systems

Significant structural differences between marine and land mammal ears are primarily found in the outer and inner ears. All marine mammals have special adaptations of the external ear (valvular canal closure mechanisms, semioccluded canals, and wax plugs) and middle ear (heavily vascularized and innervated middle ear mucosa, diminished or absent mastoids, and broad-bore Eustachian tubes) consistent with deep, rapid diving and long-term submersion. However, recent data suggest that marine mammals retain air-filled middle ears and the same fundamental inner ear components and hearing mechanisms as terrestrial species.

Cetaceans have the most derived ear of any mammal, marine or otherwise. As cetaceans evolved into obligate aquatic mammals, their head tissues were pushed, inflated, and telescoped (Barnes, L. G. *et al.*, 1985) to form a novel cranium with elongated jaws (rostrum), scooped frontal bones, and nares transposed upward and rearward, dorsal to the eyes. Telescoping may have been driven head reshaping primarily to allow minimal head exposure at the surface, but the ear was effectively dragged along with other skull elements to new positions in the

head, and profound structural changes for sound transduction took place in virtually all parts of the peripheral auditory system.

In cetaceans, sound most likely arrives at the ear via specialized fatty tissues that are coupled to the middle ear and that act as both pinnae and external canals (Figure 3). Norris K. S. (1969) speculated that a fatty core in the posterior third of the mandible acts as a preferential path for underwater sound. Recent studies have determined that these perimandibular fats have complex shapes that effectively form internal pinnae (Ketten, D. R. *et al.*, 2004). They also are composed of very unusual lipids that have physical properties consistent with acting as a specialized channel matched to the acoustic impedance of underwater sound (Koopman, H. N. *et al.*, 2006).

Cetacean middle and inner ears in general were reshaped also to meet the demands of underwater physics of sound. They became encased in distinctive, shell-shaped bony capsules (tympanic and periotic bullae) that moved outside the brain case and, at least in most modern odontocetes, lost all firm bony connections to the skull. Instead, the tympanoperiotic bullae, and thus the middle and inner ears of dolphins, are suspended by ligaments or struts in a spacious, soft tissue-filled extracranial sinus. This accomplishes two critical things for underwater hearing. First, the ears have a three- to fivefold greater separation than if they retained the intracranial position common in land mammals, which means they are separated to match the increased speed of sound in water. Second, both the middle and inner ears are acoustically isolated from most head tissues that could conduct sound to the ear which improves sound localization which is critical for echolocation.

Odontocetes and mysticetes have middle ears adapted for radically different frequencies. Odontocetes follow the ultrasonic land mammal pattern but carry it to extremes with multiple stiffening agents for the middle ear ossicles that include both well-developed stapedial ligaments and incudal struts (Ketten, D. R., 2000). Further, the tympanic membrane is substantially reduced and relatively rigid in all odontocetes. Bottlenose dolphins (*Tursiops truncatus*) have recently been shown to have middle ear stiffnesses that are sixfold greater than those of land mammals (Miller, B. S. *et al.*, 2006). All of this is consistent with audiometric data for odontocetes (discussed below) that shows broad hearing ranges from about 150 Hz to well over 100 kHz, with peak hearing over 40 kHz for most dolphins species.

Mysticetes, by contrast, have low-frequency, mass-dominated middle ears. Unlike the small, stiff middle ear and eardrum of dolphins, the mysticetes

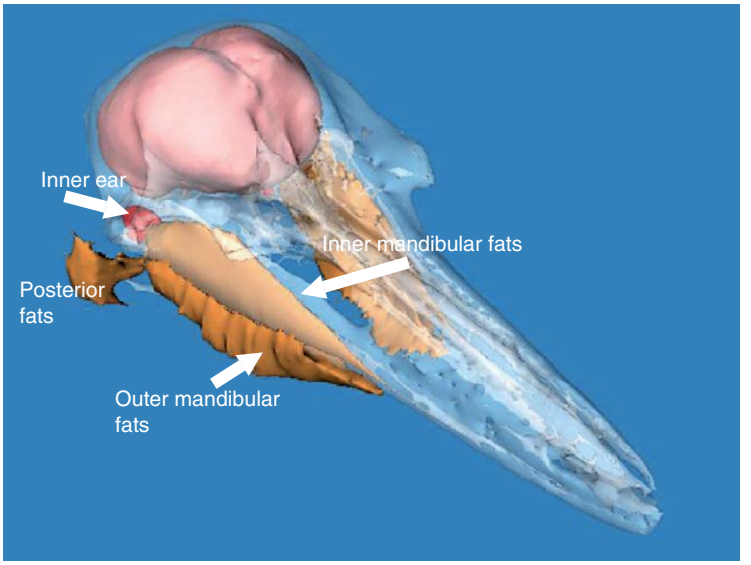

Figure 3 A three-dimensional reconstruction based on computerized tomography data of a bottlenose dolphin. The skull, including the upper and lower jaws or rostrum, are transparent to show the brain (pink) inside the skull and the ear bones (red). The ear bones, housing middle and inner ear structures, are outside the skull but inside the lower jaw (mandible) and are connected to the three fat bodies (orange) (Ketten, D. R. *et al.*, 2004, reprinted with permission, © Ketten, D. R., 2003). These fats form rabbit ears that are oriented anteriorly and slightly ventral and provide a low-impedance path to the middle ear compared to other head tissues. Reprinted by permission of Ketten, D. R.

have a thick, multilayered eardrum that is a unique elongated pouch called the glove finger (Reysenbach de Haan, F. W., 1956). This unusual structure not only reduces the probability of tympanic membrane perforation in diving but also increases middle ear volume and is coupled to a disproportionately large middle ear cavity, all of which are consistent with the expectation of good infrasonic to low-frequency hearing in most mysticetes (see Watkins, W. A. and Wartzok, D., 1985 for vocalizations and Ketten, D. R., 2000 for anatomical correlates). There is no evidence to date of echolocation by mysticetes, and whether they preceded, succeeded, or coevolved with odontocetes is not yet clear (Thewissen, J. G. M., 1998).

Thus, as a group, mysticete and odontocete middle ears span infra- to ultrasonic hearing with adaptations that clearly couple these ears so effectively to underwater sound that they may no longer be able to sense airborne sound at anything except very high levels.

There is no clear consensus on how whale and dolphin middle ears function underwater. Both conventional ossicular motion and translational bone conduction have been proposed for dolphins (see review in Ketten, D. R., 2000), and the role of the middle ear in cetaceans therefore remains an open question.

Cetacean inner ears have a well-developed spiral cochlea but substantially reduced vestibular systems. In some ways the cetacean cochlea is in fact hypertrophied in having more cells and more complex membrane structures than most land mammals. All whales and dolphins typically have more than 2000 ganglion cells mm^{-1} of basilar membrane, which is double to triple the ganglion cell densities of other mammals (Ketten, D. R., 2000). By contrast, the vestibular and optic nerves in cetaceans, in comparison to those of most land mammals, are depauperate. Cetacean vestibular systems have both far smaller canal radii than other mammals (the blue whale semicircular canals are comparable to those of mice) and very few nerve fibers. Vestibular fibers comprise less than 5% of the acousticovestibular nerve cetaceans in contrast to 40–50% in most terrestrial mammals.

In odontocetes, acute ultrasonic hearing is achieved by multiple stiffening elements in the inner ear, including doubled bony membrane suspensions and exceptional thickness-to-width basilar membrane ratios (1.0 : 0.01) that exceed even those of bats (Ketten, D. R. and Wartzok, D., 1990). Odontocete basilar membrane thicknesses typically range from 25 μm at the base to 5 μm at the apex or double those of most other species. Basilar membrane widths vary in the opposite direction; basal widths are 30–50 μm at the base and increase to 300–500 μm apically. Thus the odontocete basilar membrane is relatively thick and narrow. It therefore resembles a stiff beam throughout its length.

Mysticete membranes are thin rectangles throughout, with base-to-apex membrane ratios of 0.1 : 0.001 based on thicknesses from 7 μm at the base to 2 μm at the apex and widths ranging from 100 μm at the base (similar to the base in humans) to 2200 μm at the apex or threefold that of humans and 1.2-fold that of elephants (Ketten, D. R., 2000). These ratios are directly correlated with the resonant frequencies along the membrane, whereas the gradients reflect the octave range, which for all cetaceans implies hearing covering 10–12 octaves.

Pinniped ears are more conventional than those of cetaceans. External pinnae are reduced or absent in some species, but conventional external ear canals are present and functional at least for in-air hearing. One critical amphibious adaptation in seals and sea lions is a spiral cartilage–muscle sphincter that seals the meatus (Møhl, B., 1968), implying that the canal can be voluntarily closed. Whether the external canal remains air-filled, collapses, or floods when underwater remains unclear; neither is it known if the canal is a functional sound path to the ear in water.

The tympanic and periotic bones of pinnipeds resemble those of terrestrial mammals. The ear bones are not acoustically isolated as with those of cetaceans, and the middle ears only have a moderate layer of cavernous tissue with a wide range of ossicular chain configurations ranging from very massive (elephant seal) to moderately stiff (harbor seal; Møhl, B., 1968; Marsh, S. E. *et al.*, 2001), implying a wide variation in peak frequencies among species.

Most pinniped inner ears resemble those of terrestrial high-frequency generalists with evidence for some ultrasonic, but not well-developed, high ultrasonic hearing (Solntseva, G. N., 1990). At least one species, the elephant seal, has a membrane structure consistent with better low-frequency hearing than most other pinnipeds (Wartzok, D. and Ketten, D. R., 1999)

3.14.5.2 Marine Mammal Audiometrics

Audiograms are available for 11 of the nearly 80 cetacean species (Au, W. W. L., 2000), but the data are only from smaller odontocetes. Consistent with

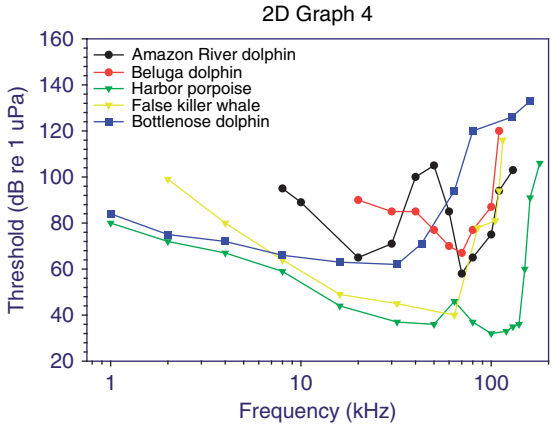

Figure 4 Hearing thresholds for a variety of odontocete cetaceans. Data for the Amazon River dolphin and the beluga dolphin (Popov, V. and Supin, A., 1990) were measured using auditory brainstem response methods. Data from the harbor porpoise (Kastelein, R. *et al*., 2002), false killer whale (Thomas, J. A. *et al*., 1988), and bottlenose dolphin (Johnson, C. S., 1967) were all obtained with behavioral measures.

the anatomically derived basilar membrane estimates, electrophysiological and behavioral measures show functional hearing ranges that span 10 octaves or more and excellent ultrasonic capacities for the species tested (Figure 4). Best thresholds measured to date typically range from 40 dB re 1 μPa to 60 dB re 1 μPa, with peak sensitivities ranging from 12 kHz in the killer whale (*Orcinus orca*) to well over 100 kHz in several species including the freshwater Amazonian boto (*Inia geoffrensis*) and the harbor porpoise (*Phocoena phocoena*; Nachtigall, P. E. *et al*., 2000; Kastelein, R. *et al*., 2002).

Ultrasonic echolocation signals produced by dolphins have been recorded from 21 species and are highly species specific, although active echolocation has been demonstrated unequivocally in only the 11 species tested to date (Nachtigall, P. E. *et al*., 2000). Virtually all parameters echolocation signals can be modified by the animal, including pulse repetition rate, interval, intensity, and spectra, given sufficient background interference (Au, W. W. L., 2000). However, the dominant normal click spectra for each species is relatively constant and ranges between 12 and 120 kHz, with source levels typically near 120–140 dB re 1 μPa but reportedly as high as 230 dB re 1 μPa (summary table in Wartzok, D. and Ketten, D. R., 1999). Species recorded to date produce species-stereotypic broadband echolocation clicks, with peak energy between 10 kHz and 200 kHz, burst-pulse click trains, and constant-frequency (CF) or frequency-modulated (FM) whistles with peak spectra from 4 to 16 kHz (Tyack, P., 1999) that appear to be used for intraspecific communication.

Functional significance for species variations in echolocation and communication signals has not been fully investigated, but habitat and peak spectra of echolocation signals are strongly correlated (Ketten, D. R. and Wartzok, D., 1990). Odontocetes that employ signals above 100 kHz tend to be inshore, estuarine, and freshwater dolphins that hunt in relatively shallow water environments such as harbors or rivers. These species locate small fish amidst tangled roots and stems in heavily silted waters. They have auditory systems adapted primarily to receive and analyze ultrahigh frequencies which have short wavelengths consistent with echolocating small, nearby objects.

Off-shore animals are generally larger, travel in highly social pods, and forage in deeper, clearer waters. These species have broader frequency-adapted ears consistent with processing ultrasonic but lower-frequency peak spectra and longer ranging echolocation signals as well as even lower mid-sonic frequency whistles for communication with podmates.

Bottlenose dolphins, the most commonly studied dolphin species, perform 6–8 dB better than an ideal receiver. Most species are capable of 1–4° azimuthal resolution, although as little as ~0.5° has been reported for harbor porpoises. Minimal intensity discrimination in bottlenose dolphins (1 dB) equals human values, and temporal discrimination (~8% of signal duration) is superior to that of humans. Frequency discrimination in dolphins is significantly better than in most mammals and is best, unsurprisingly, between 5 kHz and 60 kHz in the most common species which are mostly offshore (Popper, A. N., 1980). Intensity discrimination thresholds (ITD) for odontocetes equal those of any land mammal and decline with increasing sound level. Measured values range from 1–2 dB for bottlenose dolphins up to 3–5 dB for harbor porpoises and the Amazonian boto.

Detection of a source position, known as localization, is a third feature at which odontocetes excel. Two cues are critical for mammalian auditory system localization: differences in arrival time (interaural time) and sound level (interaural intensity). On land, the normal sound path is around the head, pinna to pinna, and thus the interaural time differences (ITDs) are calculated based on the distance

between receiver points in the head. In most mammals, this is the distance measured around the head from the center of each pinna divided by the speed of sound in air. In aquatic animals, however, sound could travel through the head via tissues with densities close to sea water.

As discussed above, anatomical evidence suggests that specialized jaw fats act as preferential, low-impedance channels that are able to carry sound to the middle ear in odontocetes. Behavioral experiments (Brill, R. L. *et al.*, 1988) found that echolocation by bottlenose dolphins is impaired if the jaws are blocked from receiving sounds by neoprene shields. These results suggest that interjaw distances are the appropriate measure for ITD values in odontocetes. The interjaw or interear distances of dolphins seem large but because of the speed of sound in water, they equate to the ear separations of larger bats, which is consistent with equally good angular resolution in both groups.

In addition to localization, detection of signals in noise is also critical for echolocation in natural environments. Critical bands and critical ratios are two measures of the ability of an ear to overcome masking, the phenomenon in which competing sounds eliminate or degrade perception of another (Yost, W. A., 1994). Odontocetes have more critical bands than most mammals and smaller critical ratios than humans or even many bats, making them better than most mammals at detecting signals in noise. The best critical ratios to date (8–40 dB) are for the false killer whale (*Pseudorca crassidens*) which is also the species that has performed best in echolocation discrimination tasks (Nachtigall, P. E. *et al.*, 2000; Supin, A. Y. *et al.*, 2003).

Recent studies using auditory evoked potentials (AEP) or auditory brainstem responses (ABR) employing amplitude-modulated stimuli (AMS) in bottlenose dolphins and false killer whales have demonstrated that odontocetes extract envelope features at higher modulation frequencies than other mammals, including humans where they are important for speech perception, particularly at low frequencies (Dolphin, W. F., 1995; Supin, A. Y. *et al.*, 2003). These data suggest that auditory central nervous system adaptations in toothed whales may include regions specialized for both low and high frequencies.

There are no direct behavioral or electrophysiologic hearing data for mysticetes, but deep ocean stationary arrays and deployable recording tags have substantially increased knowledge of mysticete sounds. In general, mysticete vocalizations are significantly lower in frequency than those of odontocetes, as hypothesized from anatomical evidence (Wartzok, D. and Ketten, D. R., 1999). Mysticete sounds are characterized as low-frequency moans (fundamental frequency below 200 Hz); simple calls (impulsive, narrowband signals below 1 kHz); complex calls (broadband pulsatile AM or FM signals); and complex, seasonally varied songs (Watkins, W. A. and Wartzok, D., 1985). Infrasonic signals, typically in the 10–16 Hz range, are well documented in at least two mysticetes, blue whales (*Balaenoptera musculus*) and fin whales (*Balaenoptera physalus*; Watkins, W. A., 1981). It has been speculated that mysticetes use infrasonic signals for long-distance communication or topographic scale echolocation, but there is not as yet any clear evidence or field tests that support the idea.

Pinnipeds are divided into three groups: Phocidae: true or non-eared seals; Otariidae: eared seals; and Odobenidae: walruses. Audiometric data show they vary from partially to fully adapted for underwater hearing (Figure 5). However, to date it is not certain how most species accomplish hearing in both media. One possibility is that pinnipeds have dual systems operating independently for aquatic and airborne stimuli and in different frequency ranges related to behaviors in each medium (e.g., feeding in water versus pup location on land). A second possibility is that pinnipeds are adapted primarily for one environment or the other or have one system for hearing in both media but not optimized for either. The current data suggest that among tested species both of these possible strategies have evolved.

The 11 pinniped species tested to date have peak sensitivities between 10 and 30 kHz, with a functional high-frequency limits up to 75 kHz (Richardson, W. J.

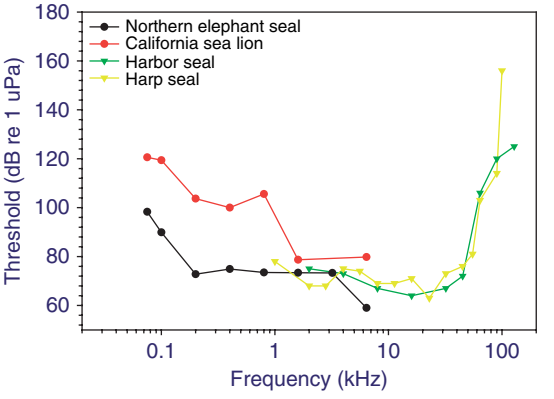

Figure 5 Underwater behavioral response auditory thresholds for four species of pinniped. Northern elephant seal and California sea lion from Kastak D. and Schusterman R. (1998); Harbor seal from Møhl B. (1964); Harp seal from Terhune J. M. and Ronald K. (1972).

et al., 1995, Kastelein, R. *et al.*, 2002; Southall, B. L. *et al.*, 2004). Low-frequency functional limits are not yet well established for most pinnipeds, but parallel studies of harbor seals (*Phoca vitulina*) versus elephant seals (*Mirounga angustirostris*) suggest that elephant seals have significantly better underwater low-frequency hearing sensitivity than other pinnipeds tested to date, with functional hearing down to 75 Hz (Kastak, D. and Schusterman, R., 1998).

In air pinniped audiograms have peak sensitivities at slightly lower frequencies than in water (3–10 kHz; Kastak, D. and Schusterman, R., 1998). Thresholds for airborne sounds are poorer, on average, in phocids, the seals, which have no overt pinna, but there is little difference in aerial versus underwater audiograms for otariids, the eared seals and sea lions. This implies that phocids may be better adapted for underwater hearing, whereas otariids evolved a single system that operates adequately but not optimally in air or water.

In frequency discrimination and localization tasks, pinnipeds perform more poorly than odontocetes. Angular resolution ranges from 1.5° to 9.0°, but most have 4.0° to 6.0° of resolution (Richardson, W. J. *et al.*, 1995). Minimal intensity discrimination (3 dB) in California sea lions is poorer than that of dolphins or humans, but frequency discrimination in phocids and sea lions is similar to that of bottlenose dolphins. Critical ratios for pinnipeds are generally equal to those of dolphins and humans. Like odontocetes, pinnipeds in water could have small-to-large functional inter-ear distances depending upon whether they use the external canal, specialized tissues, or the inner ear as the sound reception point underwater. However, to date, there are no clear data on the configuration of any pinniped underwater sound reception path.

Most pinniped sounds recorded to date are in the sonic range, and the repertoires are complex, varying by context, sex, and season (Watkins, W. A. and Wartzok, D., 1985; Richardson, W. J. *et al.*, 1995). Call descriptions run the gamut from grunts to rasps, rattles, and warbles in addition to whistles, clicks, and pulses ranging from 100 Hz to 15 kHz, with peak spectra below 5 kHz. Like cetaceans, source levels in water are commonly near 130 dB re 1 μPa although levels as high as 193 dB re 1 μPa have been reported (Richardson, W. J. *et al.*, 1995). Despite producing click-like sounds, there is no evidence that pinnipeds are able to echolocate. Infrasonic to seismic sounds are produced by northern elephant seals in air. Thus, both air and underwater vocalizations for these amphibious species, like those of cetaceans and other mammals, are consistent with conclusions from ear models and with the general characteristics of audiograms in tested species.

Glossary

cochlear microphonic An electrical field potential that originates in the summation of transduction currents of cochlear hair cells.

compressive nonlinearity A deviation from linear behavior of a system in which the amplitude of the response grows at a rate less than proportional to the amplitude of the input. This is also referred to as a saturating nonlinearity.

distortion products Frequencies generated by a nonlinear system that are not present in the input.

nonlinearity Deviation from linear behavior. Signs of nonlinearity include a compressive or expansive input-output relation and generation of distortion products.

quasilinearity A property of nonlinear systems with an input–output relation in which the slope does not change abruptly through the origin. The behavior of the system converges to linear for sufficiently small input amplitudes.

3.15.1 Introduction

Unlike other sensory receptor systems, the inner ear appears to generate signals of the same type as it is designed to receive. These sounds, called otoacoustic emissions (OAEs), have long been considered byproducts of the cochlear amplifier, the process that makes cochlear mechanics active by adding mechanical energy at the same frequency as a stimulus tone in a positive feedback process. This feature of the inner ear is one of the most important distinctions from other sensory receptors. In no other system is there such a profound collective reciprocal action of a population of sensory cells and supporting structures. In the eye, for example, the sensitivity of individual photoreceptors is essentially determined by the light absorption properties of the visual pigment, the rest of the eye serving passively to couple the light entering the pupil to the array of photoreceptors. The chemistry of the photopigments seems designed so that light absorption is virtually irreversible, so there is no apparent way for the eye to operate like the inner ear, where the receptor cells interact with accessory structures in a feedback loop to enhance sensitivity. One practical

implication is that photoreceptor mechanisms are much easier to study *in vitro* in single cells than are hair cell mechanisms, whose function is disrupted when they are removed from the intact hearing organ.

All normal cochleas appear to produce sounds in response to acoustic stimuli, for reasons that are the focus of intense discussion. OAEs are an epiphenomenon as they play no direct role in hearing. In principle, the ear could have a cochlear amplifier but not emit sounds. It is usually reasoned that, since the middle ear works efficiently in both directions and not all of the energy generated by the cochlear amplifier is dissipated within the cochlea, some of the added energy escapes through the middle ear and sets the eardrum in motion which in turn acts like a loudspeaker and radiates sounds out of the ear. But the story is much more complicated than that. There is ample evidence that OAEs are produced not only because cochleas amplify vibrations, but also because they exhibit nonlinearity. Nonlinearity is not only an essential characteristic of active cochlear mechanics, but also a hair cell phenomenon that may be manifest even when there is little or no mechanical amplification. Adding to the difficulty in understanding OAEs is the fact that they represent the collective action of a population of hair cells the size of which is not precisely known but is likely to depend on the levels of acoustic stimuli. The challenge in understanding emissions is that of adequately appreciating the entire signal chain, from the acoustics of the ear canal where evoking stimuli are presented, their propagation through the middle ear, the physics of wave motion in cochlear mechanics, the hair cell mechanism(s) that lie at the root of the phenomenon, and the summation and reverse propagation of the emission signals back out of the cochlea, through the middle ear, and into the ear canal.

Another conceptual problem in relating OAEs to active cochlear mechanics is the same as determining the cellular mechanism of the cochlear amplifier. Both are the product of a feedback loop that contains the transduction apparatus and both hair bundle and somatic motor mechanisms. So while both exhibit active gain and nonlinearity, these features may originate primarily in different components of the closed feedback loop. The loop can be opened to study the individual processes in isolated hair cells, but OAEs, active cochlear mechanics, and the cochlear amplifier itself are only features of the intact system.

There is no room for even an inadequate review of the OAE phenomenon. Individual published contributions now number in the thousands. The vast literature of OAEs can be accessed through several reviews (Probst, R. *et al.*, 1991; Shera, C. A. and Guinan, J. J., Jr., 1999; Kemp, D. T., 2007). But there are no current reviews with a focus of relating OAEs directly to active cochlear mechanics or to the cellular basis of the cochlear amplifier that are of greatest interest to those trying to understand the inner workings of the ear. I have therefore incorporated into this essay a mini review of a small part of the relevant literature that must be appreciated before this discussion can take place. My goal is to evaluate why OAEs are important, discuss how they are measured and interpreted, and examine the current limitations on both measurements and theories.

3.15.2 A Brief History of Otoacoustic Emission

One way to appreciate the importance of the OAE phenomenon is to review the state of understanding peripheral auditory mechanics at the time of the Kemp D. T. (1978) initial publication of his discovery. The picture of cochlear mechanics was still dominated by the pioneering studies of von Békésy G. (1960) in human cadavers (and those of other mammals), as well as in physical models. The basilar membrane was considered linear, passive, and broadly tuned. Many investigators were pursuing various schemes of an hypothesized second filter that could account for the frequency selectivity measured in auditory nerve fibers (Tasaki, I., 1954; Kiang, N. Y. S. *et al.*, 1965) versus Békésy's shallow mechanical tuning. The discovery of OAEs helped propel the study of cochlear mechanics into the modern era. Because so much had yet to be discovered of what is now known of the cochlear amplifier from direct studies of basilar membrane vibrations and motor mechanisms of cochlear hair cells, the acoustic emission phenomenon was interpreted largely using the time-honored black box engineering approach. The ear was probed by presenting acoustic stimuli and the characteristics of the emitted sounds were used to try to figure out what was inside the box that could produce this behavior. But now that we know much more about what is inside the box, it is important that theories and models of OAE be constrained by this new knowledge. In other words the outside-in black box approach should be paired with a comparable inside-out effort, and the theories and models that emerge must produce a satisfactory explanation of peripheral hearing mechanics, from hair cell motors to ear canal sounds. To some extent this is already being done, but there are many

examples of interpretations of OAEs that may not be consistent with well-established findings from more direct intracochlear studies. Examples abound in the OAE literature in which a theory or model that accounts for an emission phenomenon is described as though it was a proven fact, when direct demonstration of the predicted intracochlear phenomenon does not yet exist. I will attempt to examine the extent to which OAE phenomena have parallels in the cochlear amplifier and will address both the successes and failures of existing theories and models.

At the time when OAEs were discovered, a direct connection between basilar membrane nonlinearity, sensitivity, and frequency selectivity had not been established and so were initially considered separately. Evidence for mechanical nonlinearity accumulated in fragments. Insightful psychophysicists recognized that their studies of perceptual combination tones, at the frequencies of intermodulation distortion products generated by two-tone stimuli, gave strong evidence that mechanical nonlinearity was imposed on the basilar membrane by the healthy organ of Corti and that the resulting intermodulation distortion could be propagated as conventional traveling waves (Goldstein, J. L., 1967; Smoorenburg, G. F., 1972). Direct confirmation of basilar membrane nonlinearity came from the Rhode W. S. (1971; 1978) revolutionary studies in squirrel monkeys. This was also the first evidence that nonlinearity was accompanied with greater frequency selectivity and sensitivity at low levels, but there was still widespread skepticism about such heretical claims that vibrations so small could be nonlinear. Pfeiffer, Molnar, Kim, and colleagues had published evidence for mechanical nonlinearity, both in responses to combinations of click stimuli (Goblick, T. J., Jr. and Pfeiffer, R. R., 1969) and in populations of auditory nerve fibers (Pfeiffer, R. R. and Kim, D. O., 1975; Kim, D. O. *et al.*, 1979; Kim, D. O., 1980; Kim, D. O. *et al.*, 1980; Siegel, J. H. *et al.*, 1982). Dallos and colleagues provided the first evidence, albeit at high levels, that subharmonic distortion, measured in cochlear microphonic recordings, had an acoustic correlate in the ear canal (Dallos, P. J., 1966; Dallos, P. J. and Linnell, C. O., 1966). This was the first definitive demonstration that a distortion tone generated in the cochlea could be conducted through the middle ear and be radiated by the eardrum acting like a loudspeaker. In other words, Dallos should be credited with the discovery of OAE (see Kemp, D. T., 2007). While subharmonic distortion measured at 120 dB SPL may be generated by a mechanism different from emissions measured at lower levels, it is also possible that they are related. Dallos and colleagues also published the first clear evidence that outer hair cells were responsible for threshold sensitivity (Ryan, A. and Dallos, P., 1975; Dallos, P. and Harris, D., 1978), but it was not evident whether this facilitation was electrical or mechanical. Tuning curves of auditory nerve fibers sometimes appeared to show tip segments at elevated threshold with normal frequency selectivity (Dallos, P. and Harris, D., 1978). Frequency selectivity was envisioned as a feature of inner hair cells, with no direct link to sensitivity. The discovery of sharply tuned and sensitive inner hair cell receptor potentials (Russell, I. J. and Sellick, P. M., 1977) showed that these attributes were present in the mechanical input to the inner hair cells, restricting the possible mechanisms of interaction between the two hair cell populations. Despite the existence of the many pieces to the puzzle revealed in these studies, they were not sufficiently compelling to counter the dominant view, established by von Békésy, that the basilar membrane was linear, passive, and broadly tuned. Even as evidence accumulated for sharp, vulnerable basilar membrane tuning, it was not evident to some that this was the product of an active process. Passive second filter mechanisms were still invoked to account for selectivity.

Kemp's discovery helped tip the balance of opinion toward an active cochlea. OAEs, measured over the entire dynamic range of hearing, were undoubtedly mechanical. The evidence that they are generated by a frequency-selective and vulnerable mechanism originating in cochlear hair cells was clearly incompatible with von Békésy's passive and linear traveling wave. As studies emerged of basilar membrane vibrations in healthy cochleas using sensitive methods, attention among cochlear physiologists and theoreticians naturally shifted toward the intracochlear measurements of mechanics that would be the definitive experiments.

Adding to his direct contributions, Kemp also publicized the largely ignored proposal by the astronomer Gold T. (1948) that the ear possessed what became known as the cochlear amplifier. Gold's paper reviewed the phenomenon of objective tonal tinnitus, tones that are spontaneously emitted from some human ears that had appeared in the clinical literature. To Gold, these narrow-band signals indicated the presence of a highly tuned system that used positive feedback to counteract the damping of a passive mechanical resonance. If the gain is excessive, the circuit goes into self-sustained oscillation, predicting

the phenomenon now known as spontaneous otoacoustic emission (SOAE). If the feedback is carefully adjusted just shy of the point of oscillation, the amplifier has both very high gain and sharp frequency selectivity. Regenerative radio receivers based on this principle could detect faint transmitted radio signals, but were also susceptible to interference from strong signals from nearby transmitters, a sign that they could easily be driven into nonlinearity. A second filter would no longer be necessary, since the basilar membrane could exhibit high gain, sharp frequency selectivity, and nonlinearity, all three attributes of positive mechanical feedback in a real physical system. But rather than being the flash of light that spurred the study of peripheral auditory physiology into the modern era, the work of Gold was largely disregarded. So powerful was the impact of von Békésy that this strange-sounding notion of a regenerative receiver mechanism in the cochlea, proposed by an astronomer, sounded far-fetched. It was, except that Gold was right!

Inspired by Gold's ideas, Kemp discovered that acoustic stimuli could evoke acoustic emission from the ear (Kemp, D. T., 1978) and also confirmed with a physical measurement the clinical observations that the ear could spontaneously emit tones (Kemp, D. T., 1979a). One prominent characteristic of emissions evoked by transient sounds, commonly referred to as transient evoked otoacoustic emissions (TEOAE), was that they emerged with a delay that appeared to be too long to arise from the propagation delay of the traveling wave, as well as their prolonged duration. They also showed frequency dispersion, in that the highest frequencies in the spectrum of the emitted sound emerged from the cochlea with the shortest delay, followed by successively lower frequency components (Figure 1). A plausible interpretation of this finding was that the emission was generated by a bank of tuned mechanical resonators, each tuned to a slightly different frequency as Gold had predicted. The positive feedback mechanism within the cochlea would then add energy to the response to the evoking stimulus, some of which was coupled outward through the middle ear and radiated by the eardrum. Kemp's provocative discovery had virtually immediate impact and was rapidly confirmed and interpreted by several prominent scientists.

Looking back on that time, it is striking how many of the basic characteristics of OAEs and their significance were realized by the time the first international conference was held in London in the Fall of 1979 (published as *Hearing Research*, Vol. 2, nos. 3 and 4, 1980). For example, these earliest studies demonstrated that emissions exhibit relatively linear growth in amplitude with sound level below about 20 dB SPL, with

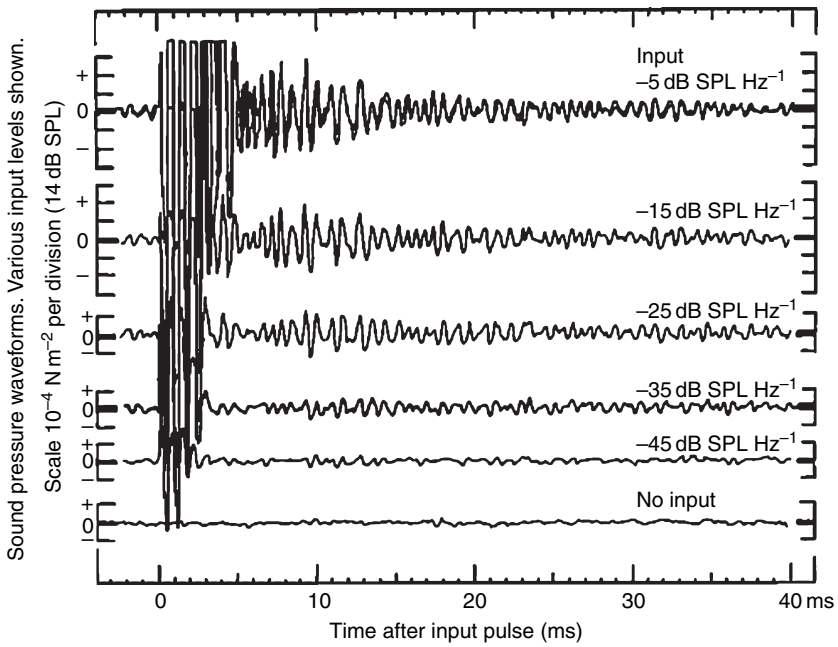

Figure 1 Otoacoustic emissions evoked by clicks from the Kemp D. T. (1978) first full report of his discovery. The delayed acoustic emission is clearly separated in time for the lowest levels of stimulation (bottom), but earlier components of the emission become evident with increasing level, but prolonged ringing of the acoustic click stimulus obscures the earliest part of the emission. Reused with permission from Kemp, D. T. The Journal of the Acoustical Society of America, 64, 1386 (1978). Copyright 1978, Acoustical Society of America.

strong saturating growth at higher levels (Kemp, D. T., 1978; Wit, H. P. and Ritsma, R. J., 1979; Anderson, S. D., 1980; Kemp, D. T. and Chum, R., 1980a), suppression by external stimuli (Kemp, D. T., 1979a; Wit, H. P. and Ritsma, R. J., 1979; Kemp, D. T. and Chum, R., 1980a; Wilson, J. P., 1980a; Kemp, D. T. and Chum, R., 1980b), and intermodulation distortion product generation with two-tone stimuli (Kemp, D. T., 1979a; Kim, D. O., 1980). The initial reports also revealed that emissions demonstrate evidence of sharp frequency selectivity (Kemp, D. T., 1978; Wit, H. P. and Ritsma, R. J., 1979; Kemp, D. T., 1979a; Wit, H. P. and Ritsma, R. J., 1980) and are vulnerable to acoustic overstimulation, hearing loss, and pharmacological agents known to impair hearing (Kemp, D. T., 1978; Anderson, S. D. and Kemp, D. T., 1979; Anderson, S. D., 1980; Rutten, W. L., 1980). Several attempts to model the new phenomenon had also appeared (de Boer, E., 1980; Kemp, D. T., 1980; Wilson, J. P., 1980b). In other words, OAEs were immediately shown to exhibit most of what are now understood to be the major characteristics of active cochlear mechanics in living ears. So direct was the presumed link that it has often been claimed that OAEs represent powerful ways to study active cochlear mechanics without having to open the cochlea. Perhaps, but the relation between the two is not as simple as usually implied. Kemp D. T. (2007) has summarized these complexities in some detail.

Although the cochlear amplifier is usually associated with the outer hair cells of the mammalian cochlea, OAEs are also present in nonmammals that lack outer hair cells and, in some cases, even a basilar membrane (reviewed by Manley, G. A., 2001). The nonmammalian emissions exhibit most of the characteristics of mammalian emissions, showing evidence for a tuned, nonlinear, and labile cochlear amplifier in nonmammals. These findings have added fuel to a lively discussion of the biophysical hair cell mechanisms that may underlie both OAEs and cochlear amplifier. For now I will focus on mammals, but will return later to a more general discussion of hair cell motor mechanisms.

3.15.3 Otoacoustic Emission Phenomena

A brief description of OAEs and how they are measured will serve as a prelude to discussing how they relate to the cochlear amplifier. Emissions are measured using the same type of device as invented by Kemp. A probe assembly containing a sensitive electret microphone is inserted into the ear canal and typically sealed into the canal using a foam ear tip to form a closed acoustic system. Sound sources are either incorporated into the probe assembly or are separate from it with the sounds coupled to the ear through small-diameter tubing. The specifics of how the emission signals are evoked, amplified, and quantified vary, but are most commonly performed using a computer-based acquisition system and standard digital signal processing procedures. It is practical to be able to distinguish emissions of –20 dB SPL or even smaller from the system's noise floor.

3.15.3.1 Spontaneous Acoustic Emission: A Response Without a Stimulus

Kemp D. T. (1979a) verified Gold's prediction of SOAEs. They have been reported for several mammals, including chinchillas, guinea pigs, dogs, monkeys, and humans. Spontaneous acoustic emission has been shown to have a correlate in spontaneous oscillation of the basilar membrane near the characteristic place of the emission frequency (Powers, N. L. *et al.*, 1995; Nuttall, A. L. *et al.*, 2004). They can be as large as 40–60 dB SPL (Ruggero, M. A. *et al.*, 1984), showing that the unstimulated ear is capable of emitting sounds with considerable acoustic power.

The spectra of the noise recorded in the ears of two humans are presented in Figure 2. The curves are slightly offset vertically (by 2 dB) to make both visible. One ear demonstrates no SOAEs, while the other emits ~11, with variable level and apparent

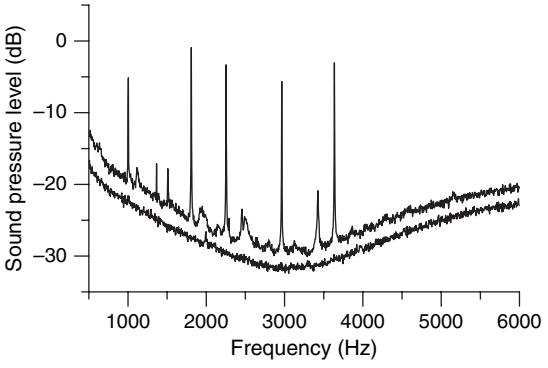

Figure 2 Spectrum of spontaneous otoacoustic emissions recorded from the ears of two humans with indistinguishable normal thresholds. One plot is displaced downward by 2 dB for illustrated. Only in one subject are spontaneous emissions present (upper plot).

bandwidth. Because these spectra are measured using long-term spectral averaging, an emission with relatively low amplitude and wide bandwidth could arise from a narrow-band oscillation that varies in frequency during averaging, but wider bandwidth for smaller emissions is predicted (reviewed by Shera, C. A., 2003). Behavioral thresholds for these two normal hearing subjects, measured using an accurate tracking method, are not significantly different over the entire frequency range of hearing and there is no indication that either individual has better hearing sensitivity in general. So while SOAEs may be absent in impaired ears, their presence is not required for normal hearing sensitivity.

3.15.3.2 Emissions Evoked by Low-Level Transients and Single-Frequency Tones

Early reports of approximately linear growth with level of OAEs evoked by low-level transient and tonal stimuli were of great interest and are even more so as reports have emerged that the basilar membrane response for characteristic frequency (CF) tones is also close to linear over the same range of stimulus level. It has become so common to associate active cochlear mechanics and OAE with nonlinearity that this low-level behavior has not been given the attention it deserves. Confusion arises because linearity at CF is also a property of cochleas in which the cochlear amplifier is not functional or at very high stimulus levels where the gain of the amplifier is small. However, nonlinearity at CF is apparent over most of the physiological range in normal living cochleas, so I will refer to the low-level behavior of both active mechanics and OAEs as quasilinear. This property characterizes many nonlinear physical systems that converge toward linearity for very small inputs. All that is required is that the slope of the function that defines the relation between the instantaneous input and the system's output should not change abruptly near the origin. That there have not been more studies of OAEs at very low levels is also partly due to technical limitations of the equipment and the procedures typically used to measure emissions.

A basic practical problem in studying OAEs is that the sound measured in the ear canal is composed of the sum of the acoustic stimulus pressure and the OAE pressure emitted by the cochlea. Click stimuli are often used so the stimulus can be separated from the emission on the basis of the time delay between the two. But emissions are often small compared to the evoking stimulus and even a well-engineered click can ring for several milliseconds, potentially overlapping the earliest part of the emission. This overlap increases as the level of the stimulus is raised, as is evident in Figure 1. Only emissions with long enough delays can be distinguished clearly from the stimulus. This fact has made it hard to study emissions originating in the basal turn that are expected to have the shortest delays, but short-latency emissions from more apical regions, should they exist, may also be obscured. This is why most studies of TEOAE do not use standard linear signal averaging. Kemp developed a clever technique to detect the presence of transient emissions that cancelled any part of the acoustic response that grows with increasing level, including most of the stimulus pressure (Kemp, D. T. *et al.*, 1986; Bray, P. and Kemp, D., 1987). A variant of this method, in which the method itself is compromised less by nonlinearity of the sound sources, has also been developed by Keefe D. H. (1998) and Keefe D. H. and Ling R. (1998). Either of these nonlinear extraction techniques removes the stimulus ringing, but unfortunately also any part of the emission that grows with level. So the technique does not measure the emission with any degree of fidelity, but only the degree to which it deviates from linear growth over a fairly narrow range of stimulus level. Because TEOAE are most commonly used in the clinic as a screening tool, only the presence or absence of an emission is at issue and the nonlinear technique works reliably for this intended purpose. But this measure of the nonlinearity of emissions is of questionable value for basic studies of emission mechanisms (Kalluri, R. and Shera, C. A., 2007).

Examining the type of experimental data used to study emissions at low levels is illuminating. To separate the stimulus and emission pressures, it is possible to estimate the stimulus pressure under conditions where the emission is negligible, using a method introduced by Kemp D. T. and Chum R. (1980b). At relatively high levels of stimulation, the pressure response in the ear canal appears to be dominated by the stimulus tone (Figure 3(a)). As the stimulus level is lowered, a periodic (with frequency) oscillation of the measured pressure around the intended value is observed, indicating the presence of a stimulus frequency otoacoustic emission (SFOAE) that goes in and out of phase with the stimulus. Plotted using the decibel scale, the fact that the pressure responses at low levels (<30–40 dB SPL) are vertically shifted versions of one another demonstrates that the amplitude of the emission

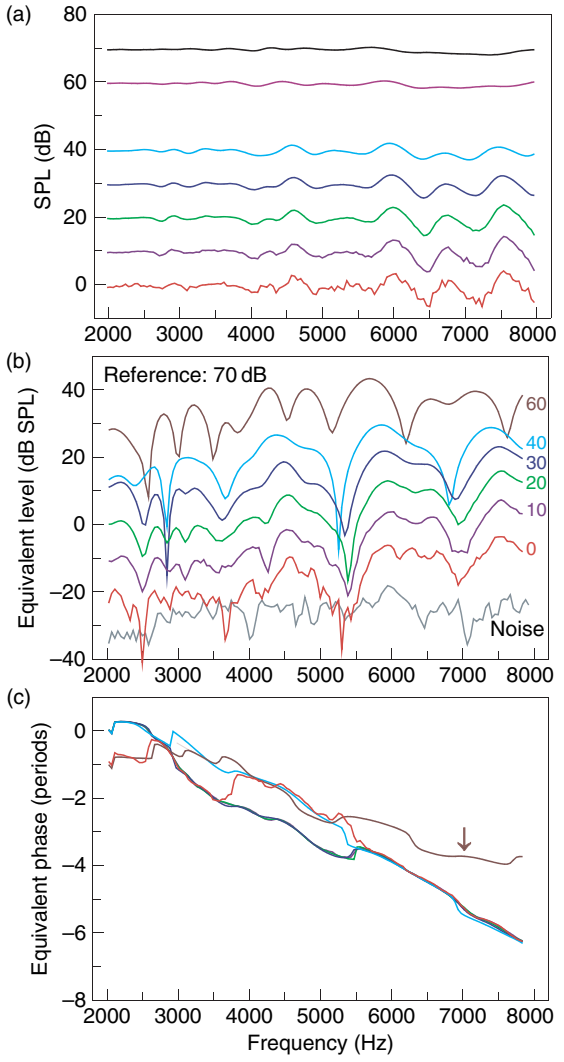

Figure 3 Stimulus frequency otoacoustic emissions measured in the ear canal of a chinchilla with normal compound neural thresholds. (a) The total pressure measured in the canal shows interaction between the stimulus tone and the emission, producing spectral fluctuations in level. The larger variations in the pressure seen with lower levels of stimulation indicate that the emission is relatively larger, compared with the stimulus, than at higher levels. Equivalent level (b) and phase (c) of the emission. The stimulus pressure is subtracted from the total pressure using the measurement at 70 dB SPL as the condition where the emission is relatively small. The level of the emission scales almost perfectly linearly with stimulus level below 30 dB SPL, but shows evidence of nonlinearity at higher levels. The phase of the emission is also relatively independent of level for stimuli below 30 dB SPL, and the overall slope is noticeably lower only at 60 dB SPL.

changes in quasilinear proportion to that of the stimulus. In these measurements from a chinchilla, there is evidence of a small contribution from the emission even at 70 dB SPL, the highest level used.

To measure the contribution of the emission at each level, the stimulus pressure is estimated by scaling down the amplitude of the pressure measured at 70 dB, then subtracting this from the pressure actually measured at each level. Since both the actually measured pressure and the stimulus estimate are vectors, the subtraction yields the vector that, when added to the stimulus pressure, yields the measured pressure. The result of this subtraction is the estimate of the emission, expressed as an equivalent SPL and phase in Figures 3(b) and 3(c). The emission magnitude exhibits regular peaks and nulls and the phase shows abrupt shifts of one half period at the frequencies of the magnitude nulls, superimposed on a general trend of increasing phase lag with frequency. The general trend in the slope of the phase in Figure 3 would be predicted if the SFOAE were delayed by around 1 ms relative to the stimulus, but the nulls and abrupt phase shifts likely represent an interference pattern between two or more signals that make up the SFOAE. As we will see later, these interactions have a behavioral correlate and likely have a mechanical correlate in the basilar membrane motion. Aside for near the frequencies of half-period shifts, the slope of the phase is remarkably independent of stimulus level, except above 5 kHz at a stimulus level of 60 dB where the slope is reduced (arrow). The magnitude grows in approximately linear proportion to the stimulus for levels of 30 dB or lower, but exhibits compressive growth at higher levels. The emission does not saturate completely.

Kemp D. T. and Chum R. (1980b) described an alternative method of separating the emission from the stimulus tone by using a second tone, near the frequency of a tone that evokes SFOAE but higher in level, to suppress the emission, leaving the stimulus pressure (see also Shera, C. A. and Guinan, J. J., Jr., 1999; Schairer, K. S. *et al.*, 2003; Siegel, J. H. *et al.*, 2005). Yet another method uses a time-domain windowing procedure that operates on the inverse fast fourier transform (FFT) or the response to the stimulus tone alone, measured across a range of frequencies (Kalluri, R. and Shera, C. A., 2001; Goodman, S. S. *et al.*, 2003). All methods yield essentially the same result, an important finding that I will return to later.

3.15.3.3 Emissions Evoked by Tone Pairs

Saturating growth of OAEs evoked by transients and tones provides evidence of cochlear mechanical nonlinearity, but the presence of two-tone distortion products and harmonics of the stimulus tones shows that the

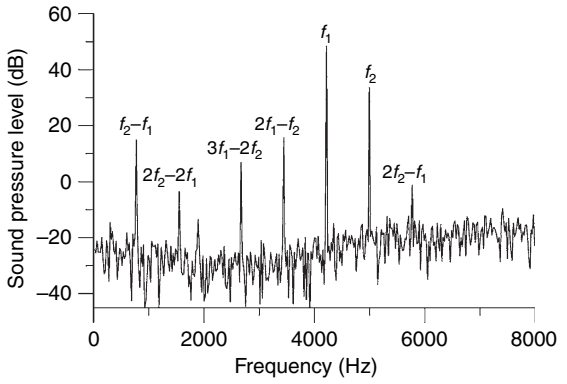

Figure 4 Distortion product otoacoustic emissions measured in the ear of a chinchilla in response to a two-tone stimulus. The frequencies of the distortion products are arithmetic combinations of the frequencies of the stimulus tones.

nonlinear mechanism(s) that generate them are fast compared to the duration of one period of the stimulus. One of the most widely used measures of OAE is to present a pair of tones (f_1 and $f_2, f_1 < f_2$) with a frequency ratio $f_2/f_1 < 1.4$. In addition to the stimulus tones the spectrum of the ear canal sound contains harmonic and intermodulation distortion products at frequencies that are simple arithmetical combinations of the two tones (Figure 4). The main practical advantage of measuring distortion products is that they are easily distinguished from the stimulus tones with narrow-band spectral analysis because they are at different frequencies from the stimuli. The most commonly measured distortion product otoacoustic emission (DPOAE) is at the frequency $2f_1 - f_2$. A problem with observing only one distortion product is the inherently incomplete information this measure provides. Not only is $2f_1 - f_2$ just one of the many distortion products that represent the emission, but each stimulus tone generates an SFOAE. Interpreting the relation between stimulus and response (i.e., all emission components together) would be difficult (reviewed by Kemp, D. T., 2007). In spite of this limitation, DPOAE has proven useful for detecting whether the cochlear amplifier and the outer hair cells that power it are normal, both in research labs and in clinical application (e.g., Martin, G. K. *et al.*, 1990; Gorga, M. P. *et al.*, 1999; Lapsley Miller, J. A. *et al.*, 2006).

3.15.3.4 Bidirectional Transduction Revealed by Acoustic Emissions Evoked by Electrical Stimuli

One of the most startling early discoveries was the demonstration that electrical currents delivered to the cochlea produce sounds in the ear canal that depend on intact hair cells (Hubbard, A. E. and Mountain, D. C., 1983; Mountain, D. C. and Hubbard, A. E., 1989; Xue, S. *et al.*, 1993; Nuttall, A. L. and Ren, T., 1995; Xue, S. *et al.*, 1995; Nuttall, A. L. *et al.*, 2001; Hu, N. *et al.*, 2005; Karavitaki, K. D. and Mountain, D. C., 2007). The extent of the region of the cochlea that contributes to electrically evoked emissions depends on how far the stimulating current spreads within the cochlea, but some place specificity results from focal current injection. It is not clear whether this phenomenon originates in somatic motility, a hair bundle motor, or some combination (e.g., Manley, G. A. *et al.*, 2001; Grosh, K. *et al.*, 2004; Chan, D. K. and Hudspeth, A. J., 2005a; 2005b). In spite of uncertainties of how to interpret electrically evoked emissions, these studies demonstrated directly that the hair cells are bidirectional transducers (Weiss, T. F., 1982) and do not simply respond passively to external stimuli.

3.15.4 Models of Otoacoustic Emission

Because of the complexity of the mechanics and cellular physiology of the inner ear, neither the cochlear amplifier nor OAEs will be understood without developing models of the ear that can account for the phenomena observed in experiments. On the other hand, models that are too abstract to formulate hypotheses that can be tested with experiments are of limited value. But a model that is designed to account for an OAE phenomenon may also have direct relevance to cellular mechanisms of the cochlear amplifier. A good example is the model developed by Shera C. A. (2003) to account for the characteristic minimum frequency spacing seen in mammalian spontaneous emissions. The model formalizes an explanation of how the passive mechanics of the cochlea and middle ear constrain the frequencies of SFOAE to particular values separated by regular intervals. Such behavior cannot arise from single hair cells in isolation, but can be modeled as a standing wave resonance produced by multiple internal reflections (see below). This strong dependence on accessory structures may distinguish active tuning mechanisms in mammals from those in nonmammals where frequency selectivity may arise from electrical or electromechanical resonance in individual cells (e.g., Crawford, A. C. and Fettiplace, R., 1985; Martin, P. *et al.*, 2001; 2003). Whatever the

mechanism of force production by hair cells, the constraints imposed by the strong coupling of individual hair cells to the passive mechanics by supporting structures, including the tectorial membrane in those hearing organs that have one, probably guarantee that the larger mechanical context must be considered. It has been proposed that mammalian outer hair cells have inherent tuning mechanisms (Fettiplace, R., 2006), but it is likely that the frequency selectivity of the active mammalian cochlea is the product of the passive mechanics of the cochlea with hair cells serving as relatively frequency-independent force generators. This is but one example of how models accounting for the behavior of OAEs, which must be understood as wave phenomena, can help evaluate models of active cochlear mechanics that incorporate force generation by hair cells.

Kemp developed a distinction between what he referred to as place-fixed and wave-fixed emissions (Kemp, D T., 1986, summarized by Kemp, D. T., 2007). He proposed that a linear, passive cochlea would dissipate essentially all of the energy of an incoming wave and no sound would be emitted in response. Even an ear with a cochlear amplifier would dissipate the added energy internally unless the forward-propagating traveling waves encountered an irregularity in the mechanical impedance of the basilar membrane. Reverse traveling waves arising from forces generated by hair cells would cancel in a smooth cochlea and only forward-propagating waves would exist. But the cancellation of reverse waves would be disrupted by impedance irregularities and reflected waves would become apparent. Spontaneous emissions and modulated SFOAE and TEOAE spectra would arise from standing waves caused by multiple internal reflections between fixed mechanical irregularities and the basal end of the cochlea (Kemp, D. T., 1979a; 1979b; see Kemp, D. T., 2007). The fraction of the energy in the forward wave that is reflected at the peak can be characterized as a reflectance. The same is true for the reflected wave when it encounters the impedance mismatch at the basal end of the cochlea. Thus, part of the energy is reflected to form a secondary forward traveling wave, while the rest enters the middle ear and is radiated into the ear canal. The secondary wave is amplified and reflected as before and so on. If the round-trip gain in energy due to the cochlear amplifier exceeds the total dissipated within the cochlea and escaping into and through the middle ear, sustained oscillation ensues. Another way of saying the same thing is that self-oscillation results when the product of the apical and basal reflectances exceeds unity. Since the reflectance at the basal end is passive and between 0 and 1, the apical reflectance can exceed 1 when the round-trip energy gain is near the point of instability. OAEs produced by this mechanism were described as place-fixed because the first reflection occurs at the place of each particular irregularity. In contrast, wave-fixed emissions were hypothesized to arise because of an impedance change created near the peak by mechanical nonlinearity. The origin of such waves would move with the envelope of the traveling wave as frequency is varied. They would be determined by the underlying wave pattern on the basilar membrane and are thus fixed to the wave. In a cochlea with a perfect logarithmic relation between frequency and place, the wave pattern simply shifts longitudinally with changing frequency, with no change in shape or even phase within the envelope. This property is termed shift symmetry. The phase of OAEs generated in this way would exhibit a shallow slope versus frequency (see also Shera, C. A. and Guinan, J. J., Jr., 1999). The underlying traveling wave delay would not be apparent in the emission. This applies to DPOAE originating in the region of overlap between the responses to the two stimulus tones if the ratio of the frequencies of the tones is fixed. Fixing the frequency of one of the two tones reveals the underlying wave propagation delays (Mahoney, C. F. and Kemp, D. T., 1995). Stimulus frequency emissions measured at levels high enough to become nonlinear would likewise be expected to exhibit shallow phase slopes versus frequency because of shift symmetry.

The most comprehensive and detailed model of OAE at present is the one described by Shera C. A. and Guinan J. J., Jr. (1999) (Figure 5). In a break with previous formulations, Shera and colleagues proposed that OAEs are the product of two fundamentally different mechanisms: linear coherent reflection and mechanical nonlinearity. Emissions are distinguished as reflection or distortion emissions corresponding to the mechanism of generation. To generate emissions with the long latencies observed for transient and stimulus frequency emissions and a delayed component of DPOAE requires a generation mechanism that is either fixed in location (Kemp, D. T., 1978) or that in some other way breaks shift symmetry. One proposed mechanism, termed the Theory of coherent linear reflection filtering (CRF) emerges as the result of small regular (Strube, H. W.,

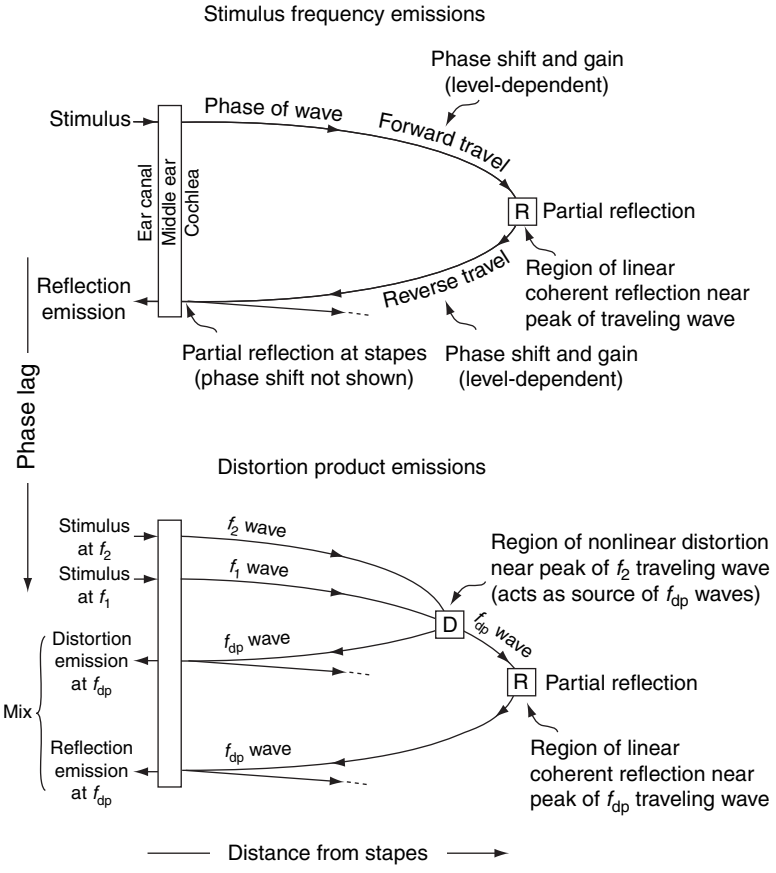

Figure 5 Classification scheme for otoacoustic emissions developed by Shera C. A. and Guinan J. J., Jr. (1999), based on their hypothesis that emissions can be distinguished based on fundamentally different mechanisms of generation. Reused with permission from Christopher A. Shera, The Journal of the Acoustical Society of America, 105, 782 (1999). Copyright 1999, Acoustical Society of America.

1989) or random (Zweig, G. and Shera, C. A., 1995) variations in basilar membrane impedance, which cause coherent reflections of forward-propagating traveling waves near the peak, but incoherent reflections from other regions that cancel one another. Coherent reflection from the peak region also depends on the fact that the peak is both tall and broad. Should the shape of the peak change, as with increasing stimulus level, suppression or other impairment of the cochlear amplifier, then the reflections should be reduced dramatically (Shera, C. A., 2004). Reflection emissions should then be especially well suited to detecting sensory cell hearing loss. Distortion emissions, measured at stimulus levels that drive cochlear mechanics into their nonlinear range, are predicted to exhibit not only different phase behavior, but different sensitivity to hair cell damage.

Both multiple internal reflection models envision the wave reflected from the apical location as a reverse version of von Békésy's traveling wave. If the reflected wave can approach and even exceed the amplitude of the incident wave, then reverse traveling waves should be readily observable, either directly in the motion of the basilar membrane or using indirect measures such as population responses of auditory nerve fibers. To date there have been no compelling experimental measurements of reverse traveling waves. The most clear-cut proof would be to observe them in longitudinal measurements of basilar membrane motion. This experiment, so far performed only in one laboratory, reported only forward-propagating waves (Ren, T., 2002; 2004; He, W. *et al.*, 2007), even in cochleas with normal sensitivity. Similarly, measurements of the basilar membrane response versus frequency at a single location should reveal the existence of standing waves for tones below CF, but this is not evident in any study of basilar membrane vibrations published till the time of

this writing. (A recent report of basilar membrane responses in chinchillas may contain the first evidence of this sort (Rhode, W. S., 2007). Quasiperiodic spectral fluctuations are noted for responses to tones at frequencies below CF at low stimulus levels, and disappear at levels above 30 dB SPL, similar to the behavior of SFOAEs in chinchillas (i.e., Figure 3).) The hypothesized reverse traveling waves should decrease in amplitude with increasing stimulus level, relative to the amplitude of the forward traveling wave, so there should be evidence of nonlinearity in I/O functions for single tones below CF, but significant deviations from linearity have not been observed in any set of data for frequencies an octave or more below CF. Conclusive data could be gathered by measuring both single tone responses in the basilar membrane and SFOAE in the same experimental animal. If reverse traveling waves exist, then wave interactions should be evident in both measures. If confirmed, this would be an example of an important cochlear mechanical wave phenomenon that was first detected in OAE measurements. Direct measurements of reverse traveling waves might then indicate that previous experiments that failed to demonstrate the phenomenon were compromised by the invasive techniques required to perform these extremely difficult experiments. But if such interactions are only present in SFOAE, then it would not be plausible to account for them with reverse traveling waves. Either basally directed basilar membrane traveling waves will eventually be demonstrated or it may be necessary to search for another mode of reverse propagation. However, until this question is resolved, it is wrong to speak of reverse-propagating conventional traveling waves and multiple internal reflections as though they are proven facts. Similar cautionary language is appropriate for describing emissions as wave- or place-fixed or in their origin using separate linear reflection or nonlinear distortion mechanisms until the physiological basis for these concepts is conclusively supported by experiments.

3.15.5 Interpreting Otoacoustic Emissions: Relation to Active Cochlear Mechanics and the Cochlear Amplifier

The background is now set to examine whether the measured behavior of OAEs directly corresponds to characteristics of the basilar membrane response attributed to the cochlear amplifier, implying a direct link. But I will first examine the question of whether what appears to be sound emitted by the ear is a cruel joke played on unsuspecting scientists by a cagy cochlea.

3.15.5.1 Emitted Sounds or a Change in the Cochlear Input Impedance?

Rather than sounds emitted by the ear, it has been proposed that OAEs can alternately be explained as the result of a passive, nonlinear modulation of the cochlear input impedance (Patuzzi, R., 1996) that is caused by intracochlear features such as nonlinear stereocilia stiffness or the action of prestin. The cochlear input impedance strongly influences the acoustic impedance of the eardrum (Zwislocki, J., 1962), so for typical high-impedance sound sources, a change in eardrum impedance will change the measured pressure. The change in measured sound pressure could equivalently be caused by the presence of a signal that is created in the cochlea. Recognizing this basic problem, Guinan J. J., Jr. (1990) suggested that SFOAE be expressed as an equivalent pressure and an equivalent phase. The change in the sound pressure for one tone induced by adding a second, more intense tone could also arise from a passive nonlinear interaction between the two tones. The concept of a nonlinear component of the eardrum reflectance, which may equivalently be considered the OAE, has been developed explicitly by Keefe D. H. (1998; Keefe, D. H. and Ling, R., 1998). But if emissions are measured at low enough levels that they become quasilinear, then they obviously cannot depend on nonlinearity. But this does not resolve the issue because a passive process that modulates the cochlear input impedance and is nonlinear may also converge to quasilinear behavior for small inputs.

The signal versus impedance explanation is not really the critical distinction. I like the way Chris Shera put it in a recent private communication: That OAE can be explained as a modulated cochlear input impedance is

> . . . right in a narrow technical sense: emissions measured in the ear canal do manifest themselves because they affect the cochlear input impedance. But saying that does not explain emissions, except in some superficial sense. Any satisfactory explanation would have to make clear how and why (i.e., through what cochlear process) the emission generation mechanisms modify the cochlear input impedance.

Regardless of whether the cochlear input impedance changes because the ear emits sounds or

because of a change in a passive and/or nonlinear component of the inner ear, if we make an impedance measurement we will measure an impedance! This is in fact the same problem as proving that the cochlear amplifier exists. If we measure the ratio of the differential pressure across the basilar membrane to the displacement caused by a tone at the characteristic frequency of the place of measurement, we can calculate the mechanical impedance at CF. If we reduce the gain of the cochlear amplifier by injecting furosemide into the blood supply to the cochlea, causing a drop in the endocochlear potential, then the same applied pressure causes much smaller displacements and the impedance is therefore much higher. Since we know that the change in impedance was caused by removing a source of power, then we also know exactly why the impedance changed. Similarly, if we inject into the fluid spaces of the organ of Corti of a living animal a substance like gelatin that increases the damping and/or stiffness of the cochlear partition, we will also measure reduced displacement for the same applied pressure and the mechanical impedance may increase by exactly the same factor as when we injected furosemide. But we know that the impedance changed in this case because we altered the passive mechanical properties of the cochlear partition. If we presented our impedance measurements to another scientist without telling how the cochlea was perturbed, then the scientist would have no way to interpret the results. In fact, consensus on the existence of a cochlear amplifier has depended not only on the discovery of motor mechanisms in hair cells or measurements of basilar membrane vibrations, but also on theories of cochlear mechanics and models that demonstrate that measured responses of the basilar membrane can only plausibly come from an active cochlea. The cochlear amplifier is a distributed phenomenon in which hair cells in a region extending basal from the peak supply the energy used to enhance the response at the peak. OAEs are likewise a distributed phenomenon that can likely be understood only through applicable theory-based models. There is as yet no direct demonstration that any hair cell motor function underlies the cochlear amplifier. So, while OAEs are one step removed from basilar membrane mechanics, the difficulties in interpreting them are fundamentally the same.

The view that emissions are signals that have correlates in basilar membrane vibrations is also supported by the demonstration that the low-level SFOAE is paired with a corresponding cochlear microphonic (Wilson, J. P., 1980b; Siegel, J. H., 2006), which is unambiguously a signal known to be generated by mechanical excitation of hair cell transduction (Dallos, P., 1973). Interpreting emission behavior at higher levels of stimulation where nonlinearity is evident is even more complex, because passive nonlinearities of the cochlea could originate in a mechanism separate from the cochlear amplifier. However, emissions that exhibit nonlinearity are usually measured under conditions where the basilar membrane is also known to demonstrate nonlinearity and disappear in situations where basilar membrane nonlinearity is abolished, so again the simplest interpretation is to assume a direct relationship. Resolving this question conclusively is beyond the scope of this contribution and will require definitive experimental data and a theory that can be proven correct.

3.15.5.2 Positive Feedback in the Mechanics of the Cochlea

Perhaps the most important insight gained from the existence of SOAE is that the ear has a positive feedback mechanism that is adjusted for maximum sensitivity, but does not allow large sustained self-oscillations that would interfere with hearing. Some mechanism appears to stabilize most SOAEs at very low levels. That SOAEs can sometimes be quite large is curious because the levels of SOAEs are typically below the threshold of hearing, even in humans where they are common. Compressive mechanical nonlinearity of the basilar membrane near CF, probably due to the saturating transduction apparatus, is likely to play a role (e.g., Talmadge, C. L. *et al.*, 2000). Whether this factor is sufficient to stabilize the amplitudes of very small SOAEs has not been established.

The amount of spontaneously emitted energy is typically so small that SOAE could represent random noise passed through a passive filter with very narrow bandwidth. Although the basis for such a sharp, passive filter was unclear, one way to approach the problem was to ask whether SOAEs represented net power production by the ear. This was accomplished definitively by showing that the power reflectance of the ear could become negative near the frequency of an SOAE, indicating that the acoustic energy emitted by the ear was greater than the power of the sounds used to measure reflectance (Burns, E. M. *et al.*, 1998; Tubis, A. and Talmadge, C. L., 1998). Strong evidence that SOAEs are noisy signals rather than filtered noise comes from statistical analyses of

SOAE amplitude distributions with time (Bialek, W. and Wit, H. P., 1984; Talmadge, C. L. *et al.*, 1991; van Dijk, P. *et al.*, 1996; Shera, C. A., 2003). These studies showed that SOAEs are incompatible with a passive filter model, but consistent with models of an amplitude-stabilized oscillator.

Multiple internal reflections were originally invoked to account for the long delays of stimulus-evoked emissions (Kemp, D. T., 1979a; 1980; reviewed by Shera, C. A. and Guinan, J. J., Jr. 1999). But it has since been shown that the delays measured for SFOAEs can be used to predict the characteristic minimum spacing between adjacent SOAEs, as well as the frequency dependence of their bandwidth and the influence of changes in the impedance of the middle ear (Shera, C. A., 2003). The power of being able to predict in such detail the behavior of SOAE from the behavior of SFOAE supports the CRF theory, but more importantly (in my view) strongly supports the notion that they originate in the same mechanism. Such a connection was proposed early on by Kemp, Wilson, and others (see Zwicker, E. and Schloth, E., 1984). Several of these studies documented that SOAE could be synchronized by external transient stimuli and that the SOAE could lock to the frequency of a nearby stimulus tone, a phenomenon described as capture (see Long, G. R. and Tubis, A., 1988). I have informally noted a strong association between SFOAE and SOAE in chinchillas. In an animal with an SOAE near 7.5 kHz, the magnitude of SFOAE evoked by tones <25 dB SPL slightly exceeded the stimulus pressure in the ear canal for frequencies near that of the SOAE. In many other cases where no SOAEs were detected, the level of SFOAEs was never larger than that of the stimulus (data not shown). The presence of strong SFOAE (or TEOAE) seems to indicate an ear that is close to being unstable.

3.15.5.3 Quasilinearity at Low Stimulus Levels

Both cochlear mechanics and OAEs exhibit quasilinear behavior at sound levels below 20–30 dB SPL. A common feature of many nonlinear physical systems is that they converge to linear behavior for very small inputs. Although nonlinear level dependence was emphasized as a hallmark of evoked acoustic emission in the Kemp D. T. (1978) first report, near-linear growth of OAEs at low levels was subsequently noted in several reports (Wit, H. P. and Ritsma, R. J., 1980; Wilson, J. P., 1980a; Kemp, D. T. and Chum, R., 1980b; Zwicker, E. and Schloth, E., 1984). Linearity is not only appealing for developing theories of both mechanics and emissions, but it may offer a situation to critically test proposed cellular mechanisms that underlie them. It was also evident to early investigators that emissions evoked by low-level tones and transients appeared to excite the same emission mechanism (Wilson, J. P., 1980a; Kemp, D. T. and Chum, R., 1980b). In a much more rigorous test, Kalluri R. and Shera C. A. (2007) have demonstrated that OAE evoked by transient stimuli and standard linear signal averaging can be predicted almost perfectly from measurements using single tones and vice versa. I believe this to be conclusive evidence that, at least for low-level stimuli, TEOAE, SFOAE (and SOAE) do in fact originate in the same mechanism.

It is also significant that widely differing methods of measuring SFOAE yield essentially the same result. One might argue that the suppression method yields a change in the response to the probe tone that appears as a signal but is instead the result of nonlinear interaction between the probe tone and the suppressor. But this explanation becomes implausible when an emission with almost exactly the same magnitude and phase is obtained using methods such as scaling and subtracting, changes in the response to the probe tone induced by the death of the animal or time-domain windowing, none of which require a simultaneous suppressor. So even for the suppression method, the change induced by the suppressor is most plausibly due to removing an SFOAE signal that is generated in the cochlea by the probe tone rather than an artifact induced by the suppressor. If SOAEs represent net power generated by the ear, in excess of that which is dissipated passively in the cochlea and middle ear, and if the levels of SFOAE can approach that of the evoking stimuli, then these linear low-level emissions are almost certainly the work of the cochlear amplifier.

As noted in Figure 3, the SFOAEs exhibit what appears to be an interference pattern of some kind. Although multiple internal reflections are one possibility, alternate mechanisms must be considered if reverse-propagating traveling waves do not exist in these conditions. At least for high-frequency regions of the cochlea, the group delay calculated from the SFOAE phase changes with frequency similar to the group delay at CF measured directly at one place along the spiral in the mechanical response or indirectly using responses of auditory nerve fibers (Siegel, J. H. *et al.*, 2005). How this similarity can come about despite the fact that emissions are a population

response is not understood. But at least in most cases, this finding demonstrates yet another strong correlation between cochlear mechanical wave propagation in living cochleas and emissions.

One of the fundamental predictions of the CRF theory is that the frequency-dependent slope of the phase of SFOAE, its group delay, should be twice the group delay measured at the characteristic place of the stimulus tone (Shera, C. A. and Guinan, J. J., Jr., 1999; 2003). This relation has been questioned based on a compilation of direct measures of mechanical group delay and comparable single unit measures (Siegel, J. H. *et al.*, 2005). In these sets of data the ratio of SFOAE and basilar membrane group delays appears closer to 1:1 than 2:1. Since then, Shera and colleagues have developed a more elaborate model that can generate both slow transverse waves and fast compression waves (Shera, C. A. *et al.*, 2005). Depending on the relative mix of transverse and compression waves, the ratio of SFOAE to BM group delays can range from practically zero to about 1.5:1. The revised group delay measures compare more favorably with model predictions but raise the question of whether the group delay prediction is robust enough to critically test the coherent reflection model, in light of both experimental and theoretical uncertainties.

Primates exhibit TEOAE and SFOAE with the longest delays of all mammals where emissions have been measured and CRF theory predicts that human frequency selectivity must be about three times sharper than small mammals (Shera, C. A. *et al.*, 2002; Shera, C. A., 2003). Using SFOAE measurements to predict frequency selectivity could be very useful. But Ruggero M. A. and Temchin A. N. (2007) have compared the best direct measures of group delay at CF for a wide range of vertebrates and do not find evidence that humans stand apart from other species. In particular, group delays calculated from direct measurements in human cadavers are remarkably similar to those measured in living chinchillas (which have much shorter cochleas than humans), despite 3–4 times longer SFOAE delays in humans. It is unfortunate that the relation between group delay at CF and SFOAE group delay may break down most clearly in a species where intracochlear measurements are impractical.

Low-level emission phenomena almost certainly have a direct correlate in basilar membrane mechanics because there are psychophysical observations that demonstrate corresponding phenomena that must be present in the outflow of neural signals via the inner hair cells. Fluctuations in behavioral threshold with frequency are clearly evident when thresholds are measured at closely spaced frequencies and this threshold microstructure is directly related to SFOAE and SOAE measured in the same ear (e.g., Kemp, D. T., 1979b; Wilson, J. P., 1980a; Long, G. R., 1984; Zwicker, E. and Schloth, E., 1984). This not only is a threshold phenomenon, but affects loudness perception at sound levels up to at least 40 dB SPL, where SFOAEs are partly saturated (Long, G. R., 1984; Mauermann, M. *et al.*, 2004). It seems very likely that the behavioral microstructure is caused by variations in the mechanical input to inner hair cells and should be observable in basilar membrane vibrations at low levels. Since the microstructure is variable even among humans with normal hearing thresholds, it may be labile and thus not easily preserved in invasive measurements of cochlear mechanics.

3.15.5.4 Nonlinear Behavior at Moderate Sound Levels

Evoked OAEs transition from quasilinear into compressive nonlinear growth over the same range of stimulus level as demonstrated in the basilar membrane at CF, hair cell, and single unit recordings. In other words, the energy in OAEs relative to the stimulus level declines in parallel with the decrease in gain of the cochlear amplifier at moderate stimulus levels ($< \sim$70–80 dB SPL). SFOAEs do not saturate fully at moderate stimulus levels, but continue to grow with increasing level in this range. This is also true of the basilar membrane for tones at CF, demonstrating that the cochlear amplifier provides some measurable gain at levels as high as 80–90 dB SPL. Intermodulation distortion products measured in basilar membrane vibrations show generally increasing level with stimulus level over this range as do DPOAE. These emissions demonstrate fast nonlinearity, but are not the product of a hard limiter, as distortion products are generally at least 20 dB below the levels of the stimulus tones. This is also the case for basilar membrane distortion products (reviewed by Robles, L. and Ruggero, M. A., 2001). Such behavior is expected if the compressive level dependence of the cochlear amplifier is caused by limited power in the feedback force generated by hair cells, rather than an overloading distortion mechanism, which would be expected to distribute stimulus energy into a much richer spectrum of distortion products than observed either in the basilar membrane or in OAEs. The frequency selectivity of the basilar

membrane also contributes by attenuating distortion products far from CF. Once again, the parallels between the cochlear amplifier and OAEs are striking.

The deviation from quasilinearity with increasing stimulus level shown in Figure 3 between 60 and 70 dB is interpreted as an SFOAE of roughly 40 dB SPL. Although the group delay derived from the slope of the phase curve in this case is somewhat smaller, on average, from that measured at lower levels, it is still far longer than predicted by nonlinear models (Talmadge, C. L. *et al.*, 2000).

The basilar membrane distortion product $2f_1 - f_2$ and others below f_1 have been shown to originate in two regions of the cochlea: the first being the region where the vibrations induced by the stimulus tones overlap, while the second is near the characteristic place of the distortion product frequency. Once generated in the stimulus interaction region, the distortion product propagated as a traveling wave as though it was present in the stimulus (Goldstein, J. L., 1967; Smoorenberg, G. F., 1972; Kim, D. O. *et al.*, 1980; Siegel, J. H. *et al.*, 1982; see Robles, L. and Ruggero, R. L., 2001). Kim D. O. (1980) was the first to propose that the DPOAE at $2f_1 - f_2$ also originated in these two regions. This was subsequently supported by several studies (Kemp, D. T. and Brown, A. M., 1983; Brown, A. M. *et al.*, 1996; Heitmann, J. *et al.*, 1998; Talmadge, C. L. *et al.*, 1999; Kalluri, R. and Shera, C. A., 2001; Dhar, S. *et al.*, 2002). When f_2/f_1 is held constant, the emission component originating in the interaction region of the stimulus tones appears to emerge with a relatively short delay, while the distortion product (DP) place component exhibits a delay similar to that of an SFOAE evoked by a stimulus tone at the frequency of the distortion product. Interaction between these two components at the same frequency but with different delays produces a microstructure similar to that seen for SFOAE. DPOAEs are thus envisioned as combinations of reflection and distortion emissions. This microstructure would only be apparent if the amplitudes of the two components are of the same order of magnitude. It is possible to separate the two components, either by selective suppression of the DP place component with an external tone or by spectral smoothing (e.g., Kalluri, R. and Shera, C. A., 2001). The DP place component is the more readily suppressed of the two (Kemp, D. T. and Brown, A. M., 1983).

Vulnerability to cochlear impairment has been used to classify DPOAE sources on the basis of stimulus level (e.g., Whitehead, M. L. *et al.*, 1992a), but it is likely that this distinction is based on the change in cochlear amplifier gain (Lukashkin, A. N. *et al.*, 2002) and the spatial spread of the stimulus tone interaction region with increased level. Both of these factors are likely to explain why DPOAE measured with high-level stimuli are relatively insensitive to mild impairment of hair cells. A basic but unresolved question is whether the distortion generation region for high-level stimuli extends beyond that required for the cochlear amplifier. Nonlinear interactions in transducer currents far basal to the peaks for the stimulus tones are evident in the cochlear microphonic (Dallos, P., 1973) and there is some evidence that two-tone interactions in SFOAE and cochlear microphonic (CM) appear coextensive (Siegel, J. H., 2006). Whether this basal region also contributes to the cochlear amplifier is unresolved.

It has been common to assume that the DPOAE is initially generated in a small region near the f_2 place, but this is based primarily on iso-suppression tuning curves, which are easily misinterpreted and are unsuited to evaluating relative contributions from different places (see Dreisbach, L. E. and Siegel, J. H., 2005). An extended generation region spreading basal from the f_2 place is supported by other studies (Martin, G. K. *et al.*, 1999; 2003; Fahey, P. F. *et al.*, 2006). Evidence that the DPOAE originates in the transduction process (Jaramillo, F. *et al.*, 1993; Carvalho, S. *et al.*, 2004; Liberman, M. C. *et al.*, 2004), combined with evidence from population studies of single auditory nerve fibers (e.g., Kim, D. O. *et al.*, 1980) further supports this view. Using the lowest stimulus levels that produce nonlinear interaction between the two tones restricts the size of the region of initial generation (Sutton, L. A. *et al.*, 1994). This strategy may be useful for trying to pinpoint regions of damage to the hair cells. At high stimulus levels, DPOAE can be measured even in the ears of recently dead animals (Whitehead, M. L. *et al.*, 1992b).

In sensitive cochleas, the basilar membrane I/O function becomes approximately linear at levels below about 20 dB SPL, where the displacement of hair bundles is about 10 nm (see Siegel, J. H., 2006). This is the range of transition between quasilinear behavior of the transducer for smaller displacements and nonlinearity at larger displacements (e.g., Kros, C. J. *et al.*, 1995; Lukashkin, A. N. and Russell, I. J., 1998; Martin, P. and Hudspeth, A. J., 2001). So the transducer function may underlie the compressive phase of basilar membrane level dependence, as

well as the appearance of intermodulation distortion in both intracochlear measures (Kim, D. O. *et al.*, 1980; Dallos, P. and Cheatham, M. A., 1989; Cheatham, M. A. and Dallos, P., 1990) and OAEs (e.g., Schairer, K. S. and Keefe, D. H., 2005; Siegel, J. H., 2006). The threshold for neural rate increase is also in this range of displacement, an inevitable consequence of the need for a depolarizing dc intracellular receptor potential, generated by transducer nonlinearity, to increase the average rate of neurotransmitter release by hair cells. It is probably not coincidental that the transition between linear and nonlinear SFOAE behavior is also at this inferred range of hair bundle displacement. To suppress an SFOAE evoked by a low-level tone, it is necessary that the amplitude of the displacement produced by the suppressor be large enough to drive the transducer into at least partial saturation (e.g., Lukashkin, A. N. and Russell, I. J., 1998; Siegel, J. H., 2006). Equal-level two-tone stimuli must also be presented at levels at least this high to generate measurable DPOAE (e.g., Schairer, K. S. and Keefe, D. H., 2005). In the transition into overtly nonlinear behavior, OAEs again mirror the cochlear amplifier and the hair cell transduction apparatus that may underlie all these forms of peripheral nonlinearity.

Stimuli that drive the basilar membrane into its nonlinear range should produce emissions via the nonlinear distortion mechanism. If distortion emissions arise from the cochlear amplifier, they should become evident for stimuli that exceed 30 dB SPL. Because distortion emissions generated in the interaction region of the stimulus tones are wave fixed, their phase should rotate slowly (Shera, C. A. and Guinan, J. J., Jr., 1999; Talmadge, C. L. *et al.*, 2000). But, as demonstrated in Figure 3, there is little evidence of contributions from a short-latency SFOAE except at considerably higher levels. Noting an essentially similar pattern in their measurements in guinea pigs, Goodman, S. S. *et al.* (2003) differentiated emission-level dependence presumably due to compressive growth of the basilar membrane response at CF from true nonlinear emissions which they detected only at much higher stimulus levels. It appears that basilar membrane compression was viewed as a slow-acting gain control, despite evidence for near instantaneous nonlinearity from basilar membrane intermodulation distortion measurements at relatively low levels. If distortion emissions (DPOAE) generated by two-tone stimuli are evident for stimulus levels exceeding 30 dB SPL and DPOAE microstructure indicates that they are of the same order as linear reflection emissions, then how is it possible that single tones do not generate short-latency emissions large enough to be detected unless stimuli are presented at 80 + dB SPL? How is it also possible that a slow-acting compressor generates significant intermodulation distortion, measured both in the basilar membrane and in ear canal DPOAE at comparably low stimulus levels? The answer may lie in yet another parallel between basilar membrane mechanics and emissions. The equivalency between emissions measured using clicks and tones noted by Kalluri R. and Shera C. A. (2007) was not limited to the quasilinear range at low levels as previously noted. They found that the equivalency extended to higher levels where the emissions exhibited compressive growth. As they noted, basilar membrane mechanics measured using clicks and tones of comparable levels are also surprisingly similar, despite pronounced compressive nonlinearity near CF (e.g., Recio, A. *et al.*, 1998; Robles, L. and Ruggero, M. A., 2001). As noted by the latter authors, this appears to parallel the observation that intermodulation distortion seldom exceeds −20 dB relative to the responses to two-tone stimuli, probably because nonlinearity is an inherent property of the active filter we call the cochlear amplifier, and the filter that reduces the levels of distortion products may also explain why responses to transient and tonal stimuli are so similar. While this parallel between basilar membrane mechanics and OAE is striking, it also suggests that in neither cochlear mechanics nor OAEs can linear versus nonlinear behavior be neatly distinguished by separate processes.

The CRF theory predicts that the condition for optimal reflection should depend critically on the shape of the peak of the traveling wave and reflection emissions should decline steeply as the gain of the cochlear amplifier is reduced, for example, as stimulus level is raised or when hair cells are damaged (Shera, C. A., 2004). This is another reason why short-latency nonlinear emissions should become dominant over reflection emissions over a relatively small range of stimulus level outside the linear range (Talmadge, C. L. *et al.*, 2000). In contrast, the phase behavior of the active basilar membrane does not change abruptly for CF stimulus tones at levels above 30 dB SPL. The phase of the response at the CF of the basilar membrane place barely budges over a 100 dB range of stimuli and the group delay at CF varies by less than a factor of 2. Comparable behavior is measured in SFOAE (Figure 3).

So to summarize the lessons learned from considering nonlinear behavior of emissions, the dual mechanism hypothesis attempts to separate the behavior of emissions into linear and nonlinear parts. On the other hand, we do not think of linear and nonlinear components of the cochlear amplifier, but of an amplifier that is compressive over most of the physiological range, but converges smoothly to linear behavior at levels less than 20–30 dB SPL. In light of what may be large deviations of basilar membrane and OAE phenomena from predictions drawn from the dual mechanism hypothesis, the apparent consistency of the level and phase behavior of the SFOAEs depicted in Figure 3 seems entirely consistent with the known response characteristics of active cochlear mechanics, but possibly not with the dual mechanism hypothesis. Relative to responses to single continuous tones, understanding intermodulation phenomena in the cochlea is considerably more complicated, particularly considering the uncertainties of defining the region of generation and how it may change with stimulus levels and the ratio of stimulus tone frequencies. This complexity can be readily appreciated by consulting attempts to model two-tone interactions (e.g., Kim, D. O. *et al.*, 1980; Shera, C. A. and Guinan, J. J., Jr., 2007; Shera, C. A. *et al.*, 2007). Single tones are rarely encountered in our natural environment, so studying the cochlea's response to complex stimuli is important. But I will confine most of my further comments to single tone phenomena because I believe that the basic issues of both OAE and the cochlear amplifier are best addressed, at least at present, using the simplest possible stimuli.

3.15.5.5 Nonlinear Emissions at Relatively High Stimulus Levels

The preceding parallels between OAEs and active cochlear mechanics may be compelling, but the biophysical mechanism of the cochlear amplifier itself is controversial and the region of generation of OAEs may extend beyond that of the active region that produces mechanical gain. One critically important fact that must be considered is that the region that participates in the amplifier in maintaining threshold sensitivity for a single tone is exceedingly small, no larger than about 0.5 mm (<200 outer hair cells) as demonstrated in a precisely controlled lesion study in guinea pigs (Cody, A. R., 1992). This is consistent with the common clinical finding of restricted and deep notches in audiograms and the steep slope of the audiogram commonly measured at the upper limit of hearing frequencies. This appears to rule out models of the cochlear amplifier that require the participation of large areas of the cochlea with hair cells contributing only a small gain (e.g., Lu, T. K. *et al.*, 2006). But the size of the population of hair cells contributing to the amplification (and nonlinear interactions) of above-threshold tones may expand beyond this estimate for threshold tones. Studies of two-tone suppression for above-threshold tones are relevant to this issue (reviewed by Robles, L. and Ruggero, M. A., 2001).

Contrasting with the restricted region of the cochlear amplifier near threshold in healthy living cochleas, it has been shown that DPOAE can be emitted at high stimulus levels, likely from a relatively large area, from ears in which the cochlear amplifier has been disabled, either following the death of the animal (Carvalho, S. *et al.*, 2004) or in mice with prestin knockouts (Liberman, M. C. *et al.*, 2004). These emissions, along with corresponding CM distortion products, have been reported to disappear rapidly following death (Liberman, M. C. *et al.*, 2004). If this is true, then the loss of both acoustic and microphonic distortion appears to be caused by dissipating the electrochemical driving force that powers the transduction current, rather than by disrupting a passive nonlinearity, perhaps inherent to the structure of the stereocilia bundles and/or gating transducer channels of hair cells. At relatively high levels (70–80 dB SPL), it appears that OAEs, even distortion products, can truly be signals actively generated by hair cells rather than exclusively the result of passive nonlinearity. It was this collection of facts that led Liberman and colleagues to conclude that hair bundles actively generate OAEs. They could not rule out the possibility that this was the dominant generator of DPOAEs even at lower stimulus levels in normal ears. The reduced emissions seen at lower stimulus levels might simply reflect the reduced mechanical drive to the hair cell transducers caused by the lower mechanical gain. But in a feedback loop such as the cochlear amplifier it is hard to differentiate cause and effect. These results demonstrate the potential for studies of OAEs to help solve the cochlear amplifier.

This scenario must, however, be tempered by studies in normal animals in which, at high (~75 dB SPL) stimulus levels, the postmortem decline in DPOAE is far more gradual (i.e., several hours; Whitehead, M. L. *et al.*, 1992b). At high enough levels truly passive distortion is observed, possibly

generated in the middle ear (Whitehead, M. L. *et al.*, 1992b). Further study is needed to determine whether the cochlear amplifier, both its gain and nonlinearity, are completely abolished by the above manipulations. Small OAEs measured in these animals may correspond to residual activity of the cochlear amplifier. The apparent discrepancy may be more a difference in culture and methodology between those who study OAEs and those who make intracochlear measurements. For example, the methods used to measure emissions are capable of detecting deviations from linearity as much as 100 dB below the stimulus levels, but clearly above the noise floor. On the other hand, observing a decline in cochlear amplifier gain of 95% (−26 dB) may lead one to conclude that active mechanisms have been abolished. Rigorous and applicable quantitative comparisons are required.

Because of the importance of the vulnerability of these high-level signals, it is especially important to verify that they are not artifacts that originate in the measuring system. While it is common practice to minimize distortion in the stimulus by using separate sound sources, nonlinearity in the microphone, its associated electronics, and data acquisition hardware and software can also generate artifacts. It is therefore essential to demonstrate that these passive emissions depend on the presence of intact hair cells. This is not trivial, since some manipulations such as perfusing the cochlea with fixative alter the passive mechanical properties of tissues and thus change the acoustic input impedance of the cochlea, which can influence the levels of artifact generated by the measuring system.

3.15.6 Cellular Mechanisms of Otoacoustic Emission Generation

The current debate over whether hair bundle or somatic motors produce the force required by the cochlear amplifier is equally relevant to the biophysical origin of OAEs. The cochlear amplifier ultimately derives its power source from the electrochemical gradient created by the stria vascularis. For the transduction current, this amounts to about 150 mV across the apical membrane. This driving force would be even higher, in excess of 200 mV, if the calcium component of the transducer current drives the amplifier (Chan, D. K. and Hudspeth, A. J., 2005a). A simple calculation verifies that either of the proposed motor mechanisms could generate forces large enough to account for OAEs, at least for low to moderate stimulus levels. For example, the force generated by active movements of hair bundles in the mammalian cochlea is reported to be about 500–1000 pN per outer hair cell (Kennedy, H. J. *et al.*, 2005). A recent estimate of the stiffness contributed by the hair bundle to the total stiffness of the cochlear partition indicates that the stiffness of the hair bundle and of the basilar membrane + organ of Corti are comparable (Chan, D. K. and Hudspeth, A. J., 2005b), so forces generated in the hair bundle could be delivered effectively to the basilar membrane. Nonmammalian hair bundles appear to generate an order of magnitude less force (e.g., Ricci, A. J. *et al.*, 2005). If the force generated by 200 outer hair cells was applied directly to the human eardrum, the resulting sound pressure level would be in the range of 50 dB SPL. Prestin motors generate around 0.1 nN mV^{-1} in a single OHC (Iwasa, K. H. and Adachi, M., 1997), so with a membrane voltage swing of 10 mV, this would produce a force comparable to that of the hair bundle motor. Of course the primary function of the cochlear amplifier (and the energy produced by it) is not to generate OAEs, but it speaks to the plausibility that either or both cellular motors may contribute to OAE. It is virtually certain that the mechanoelectrical transduction process controls the signal that drives prestin, but if the cochlea has evolved a solution to the high-frequency voltage attenuation problem (Santos-Sacchi, J., 1992), then contributions to OAEs could also originate in somatic electromotility (Brownell, W. E., 1990).

Close parallels between the cochlear microphonic potentials and evoked OAEs suggest a strong relation between the transducer currents of the population of contributing hair cells and acoustic emissions (Wilson, J. P., 1980b, Kemp, D. T. and Brown, A. M., 1984; Siegel, J. H., 2006). Like the cochlear microphonic, OAEs do not appear to be low-pass filtered, as would be expected for a current- rather than voltage-driven mechanism. This observation may indicate a fairly direct link between transduction currents and forces generated by the hair bundle motor, but this is far from being settled.

A critical question is which cellular mechanism can account for active mechanical action at threshold at high frequencies. Although the force generation capacity of proposed motors is an essential question, another is whether either one is ruled out by considering signal to noise ratio. There is strong evidence that the current model of hair cell transduction accounts for the threshold

performance of the system. The limit is determined by how strongly displacements of the hair bundle modulate the stochastic behavior of transduction channels (Martin, P. *et al.*, 2001). The animal can only detect the presence of a signal if there is strong enough modulation of transduction channel activity in the population of responding hair cells to be translated into a sufficient change in neural activity. The noisy transduction currents resulting from threshold stimulation in turn causes changes in the membrane potential of hair cells, but basolateral channel activity in quiescent hair cells adds another source of noise that is independent of transducer activity until synchronized transducer currents are large enough to create voltage changes in hair cells that are significant compared with the noise of the basolateral membrane caused by channel activity. Furthermore, the cochlear amplifier must produce its full gain for signal levels of 0 dB SPL and lower. The clear presence of microphonic and OAE signals below 0 dB SPL only confirms the obvious. If prestin is the cellular mechanism of the cochlear amplifier (and perhaps of OAE as well), then there must be an ac receptor potential that is sufficiently large compared with the voltage noise of the basolateral membrane to synchronize the activity of prestin motors. This must be true for frequencies as high as 100 kHz to account for hearing in bats and dolphins. Solving the low-pass filter problem for somatic electromotility requires not only a means of enhancing the ac voltage across the basolateral membrane, but also establishing a sufficiently favorable signal to noise ratio. An ac voltage of a few tens of microvolts (Fridberger, A. *et al.*, 2004) would be of little significance to hearing if the intracellular noise voltage were several orders of magnitude larger. The estimate that as few as 100 hair cells are required to account for cochlear threshold sensitivity to a tone places a bound on how much gain in signal to noise ratio can come from averaging the active mechanical contributions of a population of hair cells. Any scheme to counteract the capacitive reactance of the basolateral membrane with the electrical equivalent of an inductance transformed from the mechanical to the electrical domain through a bidirectional transducer must face the fact that the transformed impedance is subject to noise generated by the transducer. There would seem to be no benefit to increasing the ac receptor potential by raising the impedance of the basolateral membrane by canceling the capacitive reactance if the transformed inductance further degrades the signal to noise ratio.

The voltage attenuation problem is crying for the development of more biophysical-based models. But it is also not proven that a stereocilia motor can account for the cochlear amplifier or OAEs at 100 kHz. Just because the transducer is fast enough does not prove that active feedback from the hair bundle is comparably fast.

3.15.7 Conclusions and Future Directions

The numerous striking parallels between the behavior of OAEs and active cochlear mechanics suggest that emissions and the cochlear amplifier share a common origin. Understanding emissions is important not only because they can potentially tell us something about active cochlear mechanics, but also because they can be measured readily in humans and used as part of a diagnostic protocol to define the origin of hearing loss. In contrast to invasive direct studies of cochlear mechanics OAEs can be measured routinely without damaging the delicate workings of the inner ear. Studying either of these complex phenomena is hard partly because a wide range of disciplines must be focused on different aspects of the problem. Both involve wave phenomena that can only be adequately understood by applying principles of physics and engineering. At the other end are the cellular and molecular processes that require vastly different approaches. Each of us enters speaking the language we were trained to use and there is a great danger of constructing something of a Tower of Babel.

More clarity and precision are needed when describing emission data and theories to avoid circular reasoning. Those of us who live more in the experimental end of the spectrum need to have a firm enough understanding of the theories to know how to design experiments that can test them. Understanding either the cochlear amplifier or OAEs requires the use of theory and models. The system is far too complicated to solve through intuition. Experimental data are easy enough to describe, but seldom easy to interpret. We experimentalists have an obligation to acknowledge the practical limitations of our findings, particularly in the face of potential artifacts. For example, it is more useful to give a lower bound on the amplitudes of possible reverse traveling waves in the data we collect, due

to limits on our ability to detect them above the noise floor of our measuring system, than to claim that such waves do not exist. Those who live more in the theoretical domain have similar obligations. Until such major predictions of emission models such as reverse traveling waves, random impedance variations, and distinct linear and nonlinear mechanisms of emissions become firmly established in direct measurements of cochlear mechanics, it is important to make it clear that descriptions such as wave- versus placed-fixed or reflection versus distortion emissions are properties of the models developed to account for OAEs, but not necessarily of the actual cochlea. Future progress will depend not only on using better language, but also on focusing on the real question of whether OAEs arise in a fairly straightforward way from the cochlear amplifier. This does not mean that developing adequate theories and models will be easy, but neither is the problem of successfully modeling the cochlear amplifier. I suspect that OAEs will continue to prove their worth as ways to test cochlear models, but the burden is on those of us who study emissions to establish that they can be used this way and that trying to relate them to the cochlear amplifier is not a hopeless enterprise.

The dual mechanism model of Shera and Guinan is undoubtedly successful in reproducing a number of OAE phenomena, but is it a unique solution? Can a model that separates linear and nonlinear behaviors apply to active cochlear mechanics where the two properties appear to arise in a common mechanism? What may appear in the ear canal to suggest reverse-propagating conventional von Békésy traveling waves may be something else that cannot be easily distinguished from traveling waves. Whatever alternate theory might be proposed would have to do at least as well as existing theories and models. While existing models that assume shift invariance cannot account for emission phase behavior, it is not proven that the cochlea is such a system. Until it is proven that a single mechanism of OAE is positively ruled out, it is premature to conclude that two mechanisms are required. If our livelihood depends on acquiring a duck, then it behooves us to positively verify that an animal that looks, walks, and quacks like a duck really is a duck.

No active cochlear model yet exists that accurately replicates both cochlear partition mechanics and also incorporates detailed biophysical models of hair cells complete with prestin and hair bundle motors. Outside-in black box models of the OAE phenomenon have proven worthwhile, but a complimentary inside-out model intended to solve the cochlear amplifier from known properties of cochlear mechanics and hair cell force generation is critically important. To accomplish this would be a monumental achievement but is probably only a matter of time and effort. It is possible that such a model would also exhibit all the major OAE phenomena. If so, then it may well be possible to extract far more information about the workings of living cochleas from OAEs, both in the laboratory and in clinical practice, than is now possible.

3.16.1 Introduction

Each passing moment we are bombarded with information traveling in the form of light, sound, motion, and chemical signals. The rate at which the information arrives is so high and continuous that it would overwhelm the largest, fastest supercomputer ever built in short order. Yet, we expect our sensory systems to sort through the onslaught on a moment-by-moment basis and provide us with the small fraction of information that is most crucial to the task at hand. The fact that you are able to comprehend these words right now, whether transmitted in written or spoken form, attests to how remarkably well these systems work. The critical first step in this incredible process is sensory transduction, the conversion of physical information into electrical information, the language of the brain. Within the inner ear sensory transduction converts mechanical information carried by sound and head movements into electrical signals. The feat is accomplished by an array of exquisitely engineered mechanoreceptor cells, called hair cells. How hair cells transduce the enormous quantity of mechanical information that strikes the inner ear is the focus of this chapter.

Hair cells reside within patches of sensory epithelium distributed amongst the six end organs of the mammalian inner ear: one auditory organ and five vestibular, or balance, organs. Although the mechanical information transduced by each organ arrives in different forms (namely sound, rotational and linear head movements, and gravity), the fundamental mechanism by which hair cells convert mechanical energy into electrical energy is the same. Auditory and vestibular organs gain their sensitivity to the different modalities of inner ear stimuli through the anatomy and mechanics of accessory structures that serve to focus stimulus energy onto mechanosensitive hair cells. Although there are some interesting differences among hair cells of different organs and species, this chapter will focus primarily on the features of mechanotransduction common to all hair cells.

3.16.2 Hair Bundle Anatomy

The central player in the process is a mechanosensitive organelle, termed the hair bundle, which towers high above the apical surface of the cell body. The hair bundle, so named because it resembles the punkish coiffure proudly displayed atop the upper extremities of nonconformist youth (Figure 1(a)), actually consists of a staircase array of modified microvilli (Figures 1(b) and 1(c)) known as stereocilia. The stereocilia range in length from just over 1 μm up to ~40 μm, and the number of stereocilia per hair bundle ranges from 30 to 300. Each stereocilium contains a rigid bundle of actin filaments, cross-linked by fimbrin and espin, that taper at the base where it inserts into the apical surface, or cuticular plate of the hair cell (Figures 1(d) and 1(e)). In vestibular cells and immature auditory cells there is a single true cilium, called the kinocilium, that defines bundle orientation and serves to mechanically couple the hair bundle to overlying structures (Figure 1(c), arrows). Although the number, diameter, length and configuration of hair bundle stereocilia, and the presence of a kinocilium vary both within a single hair cell organ and between organs and species, they all have the same common function: to convert mechanical deflections into electrical signals.

3.16.3 Biophysics of Hair Cell Transduction

The unique cytoarchitecture of the sensory hair bundle allows the rigid stereocilia to pivot at their insertion points, causing the entire hair bundle to swing back and forth as a unit in response to mechanical forces applied at the tip of the bundle. Interestingly, the hair bundle is only sensitive to the vector component of forces applied along a bilateral axis of symmetry which runs parallel to the staircase array of stereocilia and bisects the kinocilium. By convention, hair bundle deflections toward the tallest stereocilia are defined as positive and tend to excite the cell, whereas deflections in the opposite direction are negative and tend to inhibit the cell. Hair bundle deflections 90° off the sensitive axis evoke no response (Figure 2(a)).

Positive deflections of different amplitudes evoke responses of different sizes (Figure 2(b), left panel). By

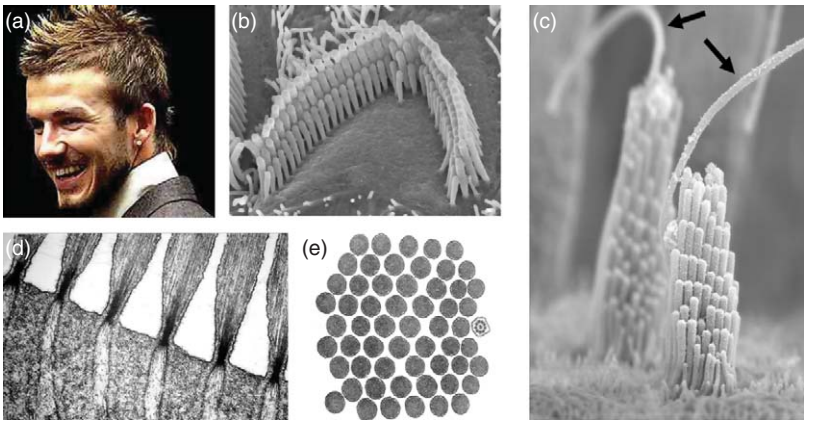

Figure 1 Hair bundle anatomy. (a) An example of a punk-style haircut which resembles the bundle arrangement of hair cells. (b) Scanning electron micrograph of an outer hair cell bundle of the guinea pig; the v arrangement of the three rows of stereocilia are evident. (c) Hair bundles from the mouse utricle; this scanning electron micrograph shows the staircase organization of the stereocilia and the presence of the kinocilium (arrows), the only true cilium in the bundle and a peculiarity of vestibular and immature cochlear hair cells. (d) Transmission electron micrograph of a hair bundle from the goldfish saccule. This longitudinal section shows the tapering of the stereocilia at the insertion into the cuticular plate. The stereocilia are filled with high density packed actin filaments that insert into the cuticular plate, forming rootlets. (e) When viewed in cross section, the hexagonal arrangement of stereocilia can be seen, as highlighted in this thin cross section of a bullfrog sacculus hair bundle; the kinocilium is located at the right with its 9 + 2 microtubule internal structure. Figure 2 Biophysical properties of mechanotransduction in hair cells. (a) Directional sensitivity of mechanotransduction: receptor potentials recorded from a vestibular hair cell; the bundle was deflected along different axes as indicated. The maximal response was evoked for bundle deflections along the morphological axis of symmetry. (b) Amplitude sensitivity of mechanotransduction. Transduction currents recorded from a frog saccular hair cell, evoked by triangular mechanical stimuli of different amplitudes (left panel). Current-displacement relation from data in left panel is fitted with a second-order Boltzmann equation (right panel). (c) Fast activation of transduction current. The left panel shows fast activation kinetics of transduction currents from a vestibular hair cell stimulated with a fast probe. Time constants of single exponential fits to current activation are plotted versus stimulus amplitude (right panel). (d) The hair cell mechanotransduction channel is a nonselective, cation permeable channel. A plot of transduction currents measured at various membrane potentials shows that currents reverse around 0 mV. (a) From Shotwell, S. L., Jacobs, R., and Hudspeth, A. J. 1981. plotting the peak response as a function of stimulus amplitude, a stimulus–response relationship can be generated that reveals several noteworthy features (Figure 2(b), right panel). The relationship is sigmoidal and often best described by a second-order Boltzmann relation. The sensitivity of the cell is defined by the steepness of the curve at its midpoint, that is, the point at which 50% of the maximal response is evoked. Cells with a greater slope are more sensitive. The relationship also reveals the operating range of the cell, often measured as the deflection amplitude required to evoke between 10% and 90% of the response. Depending on the length, width and spacing of the stereocilia, the 10–90% operating range varies from ~100 nm in basal-turn cochlear hair cells (Russell, I. J. and Richardson, G. P. 1987; Kros, C. J. *et al.*, 1992) to a couple of microns in vestibular hair cells (Holt, J. R. *et al.*, 1997). However, differences in hair bundle geometry can be accounted for by using stereocilia length and width and interstereocilia distance to calculate the gamma factor (Jacobs, R. and Hudspeth, A. J., 1990). The product of gamma and the 10–90% operating range demonstrates that the sensitivity of the transduction apparatus at the tip of the hair bundle is remarkably similar even for diverse hair bundle geometries, species and organs (Holt, J. R. *et al.*, 1997). The stimulus–response relationship also reveals a nonzero open probability (P_o) at rest. In hair cells studied *in vitro* with perilymph-like solution (normal extracellular Na^+ and K^+, high Ca^{2+}) bathing the apical hair bundles, the open probability at rest is about 0.05–0.15, so that 5–15% of the transduction channels are

open in an undisturbed hair bundle (Holt, J. R. and Corey, D. P., 1999). In a frog saccule preparation with the hair cell's overlying accessory structure intact, the resting opening probability was found to be 0.15–0.20 (Corey, D. P. and Hudspeth, A. J., 1983). The open probability (P_o) may be even greater, up to 0.5, in outer hair cells from basal turns of the cochlea *in vivo* (Russell, I. J. and Kossl, M., 1992; Legan, P. K. *et al.*, 2000; Zou, Y. *et al.*, 2006). The resting P_o varies as a function of intracellular calcium concentration, which is largely determined by the extracellular calcium concentration (Corey, D. P. and Hudspeth, A. J., 1983; Hacohen, N. *et al.*, 1989; Crawford, A. C. *et al.*, 1991). Higher calcium concentrations favor a lower P_o. The significance of the nonzero P_o for sensory signaling in hair cells is threefold. It allows the hair cell to respond to bundle deflections in both directions. When the bundle swings from its rest position toward the shortest stereocilia, in the negative direction, the current that was on at rest declines. Conversely, when the bundle swings in the positive direction the response rises. The nonzero resting P_o also functions to position the hair bundle within a steeper region of the stimulus–response relationship. In other words, it allows the cell larger responses for smaller bundle deflections than if the resting P_o were closer to zero. Lastly, the pronounced asymmetry allows the cell to generate sustained depolarizing receptor potentials, which are particularly important at high frequencies because they promote neurotransmission at the afferent synapse.

Hair cell transduction currents have a reversal potential close to 0 mV (Figure 2(d)), which suggests the channels that carry the current are nonselective. Ion replacement experiments have revealed that the channels are permeable to monovalent and divalent cations. *In vivo*, the extracellular solution that bathes the hair bundle, known as endolymph, is high in potassium and low in sodium. Thus, transduction currents are carried mostly by potassium and calcium. At typical hair cell resting potentials, which range between −60 to −90 mV, the current is inward. *In vitro*, the maximal transduction current amplitudes range between ∼−200 pA in mouse vestibular cells and ∼−2 nA in gerbil auditory cells (Holt, J. R. *et al.*, 1997; 2002; He, D. Z. *et al.*, 2004). Inward transduction currents depolarize the cell with graded receptor potentials as large as 50–60 mV. Since mature hair cells do not express sodium channels, they do not fire action potentials and thus the sensory information is encoded within the receptor potential waveform. Under physiological conditions hair cells do not depolarize positive to the reversal potential of the transduction current.

Activation of hair cell transduction is extremely fast (Figure 2(c)). When chilled to 4 °C, the activation kinetics of frog saccular hair cells were found to be as fast as ∼100 μs, leading Corey D. P. and Hudspeth A. J. (1979) to hypothesize that hair cell transduction involves a direct gating mechanism of a mechanically sensitive ion channel. Although a provocative suggestion at the time, rapid submillisecond activation kinetics has proven to be a hallmark of nearly every mechanosensitive ion channel examined since. Furthermore, the rapid gating kinetics of hair cell mechanotransduction is in stark contrast to the sensory modalities of vision and olfaction, which make use of slower (100s of ms) second-messenger, G-protein-coupled cascades. The transduction process needs to be fast, as slow biochemical cascades would greatly restrict the frequency detection limit of the hair cell. Humans can hear sound frequencies up to approximately 20 kHz and some species of bats and marine mammals can detect frequencies up to 150 kHz (Hudspeth, A. J., 1989; Torre, V. *et al.*, 1995), which necessitates submicrosecond activation kinetics. Measurements from mammalian cochlear hair cells revealed response latencies of as fast as 10 μs, the limit of the recording device (Ricci, A. J. *et al.*, 2005).

Several experiments have revealed estimates of single-channel conductance for the hair cell transduction channel. Based on high quality whole-cell recordings from cells in which the transduction apparatus was disrupted to the extent that only a single transduction channel remained functional, Géléoc G. S. *et al.* (1997) measured single-channel conductances of ∼112 pS. Interestingly, other investigators have noted that single channel conductance varies tonotopically along the length of the turtle and rat auditory organs (Ricci, A. J. *et al.*, 2003; Beurg, M. *et al.*, 2006). In rat outer hair cells the single-channel conductance was found to be 95 pS at the low frequency end and increased to 139 pS toward the middle frequency range (Beurg, M. *et al.*, 2006). By comparison, the single-channel conductance in rat inner hair cells showed little variability and was ∼170 pS. The heterogeneity in the single-channel properties of hair cell transduction suggests that there may also be heterogeneity in the molecular composition of the transduction channel (see Section 3.16.8.6). In addition, the estimates of single-channel conductance have been compared to measures of whole cell conductance to determine the number of transduction channels per cell which range from 50 to 100, or 1–2 channels per stereocilium.

3.16.4 The Gating-Spring Model

Corey D. P. and Hudspeth A. J. (1983) considered various models to describe the transduction process based on the experimental response characteristics of hair cells from the bullfrog sacculus, a ground-borne vibration detector. The model that best fit their data involved a direct coupling between stereocilia displacement and transduction channel gating. In this model, stereocilia displacement directly regulates the energy difference between the open and closed states of a mechanosensitive transduction channel, in a probabilistic fashion. This is similar to the effect of membrane potential on charged amino acids of voltage-gated ion channels. Importantly, the rate of channel opening and closing is dependent on the magnitude of the displacement. The rate is also dependent on temperature. The stimulus–response relationship was found to be an asymmetric sigmoidal curve that was best fit by a three-state kinetic model, with two closed states and one open state (Corey, D. P. and Hudspeth, A. J., 1983).

The original model postulated the existence of an elastic element, termed a gating spring, that controls transduction channel gating (Corey, D. P. and Hudspeth, A. J., 1983; Howard, J. and Hudspeth, A. J., 1987). The gating-spring model is consistent with the response latency of the hair cell (requiring time to increase tension in the spring); the asymmetric sigmoidal relationship between steady-state transduction current and bundle displacement; and the dependence of the rate of gating on displacement stimulus size and on temperature. Corey, D. P. and Hudspeth, A. J. also noticed that, while channel opening becomes faster for larger positive displacements, negative displacements beyond a certain distance do not affect the amplitude or speed of the instantaneous receptor current. This implies that the gating spring is not a rigid element, but instead becomes slack during large negative displacements (Corey, D. P. and Hudspeth, A. J., 1983). The gating spring is therefore similar to an elastic string, in that a tensile force can be exerted, but not a compressive force (Figure 3(a)) In the three-state model, one of the closed states is thought to represent the transduction channel without tension on the gating spring, while the second closed state signifies a tensioned spring, but closed channel, and the third an open channel (Figure 3(b)). The biophysical data estimate that the gating spring has a stiffness of approximately 1 mN m^{-1}; should withstand forces of greater than 100 pN; and stretch to more than twice its resting length of ~150 nm (Shepherd, G. M. and Corey, D. P., 1994; Kachar, B. *et al.*, 2000). According to the model, the stiffness of the gating spring determines the steepness, or slope, of the $I(X)$ curve (Figure 2(b), right panel). The location of the curve along the displacement axis is determined by the tension of the spring at the resting bundle position.

3.16.5 Tip Links

Soon after the seminal publication of the gating-spring model, Pickles J. O. *et al.* (1984) noticed the presence of extracellular cross-links located at the tips of hair cell stereocilia (Figures 3(c) and 3(d)). These links, visible in both scanning and tunneling electron micrographs, were later termed tip links. Tip links connect the tip of the shorter stereocilium in one row to the side of the adjacent taller neighbor in the next row. The tip links are oriented along the hair bundle's axis of sensitivity and thus are ideally positioned to act as the biophysically defined gating spring. Deflecting the hair bundle towards the tallest row of stereocilia would stretch, or increase tension in the tip links and lead to channel opening. Deflecting the hair bundle in the negative direction, towards the row of shortest stereocilia, would relieve tension and allow the channels to close (Pickles, J. O. *et al.*, 1984). Off-axis displacements of the bundle would have little effect on tip link tension. Tip links are also sensitive to calcium chelators such as BAPTA, as well as lanthanum (Assad, J. A. *et al.*, 1991; Goodyear, R. and Richardson, G., 2003) and the protease elastase.

The tip link gating-spring model, then, fits both the biophysical and ultrastructural data. Consistent with the hypothesis that tip links were the biophysically defined gating springs, Assad J. A. *et al.* (1991) found that treating hair bundles with BAPTA eliminated tip links without otherwise adversely affecting hair bundle structure, as viewed in electron micrographs (Figure 3(c)). BAPTA solutions also abolished the mechanosensitivity of the hair bundle, causing a rapid loss in transduction currents (Assad, J. A. *et al.*, 1991). Perfusion of a low calcium solution (<1 μM) onto the hair bundle can similarly abolish mechanotransduction (Crawford, A. C. *et al.*, 1991). Secondly, a resting tension is exerted on the ends of the tip links by an adaptation motor (discussed in the next section) that tends to pull the hair bundle in the negative direction by approximately 130 nm. Indeed, applying BAPTA breaks tip links and allows the bundle to

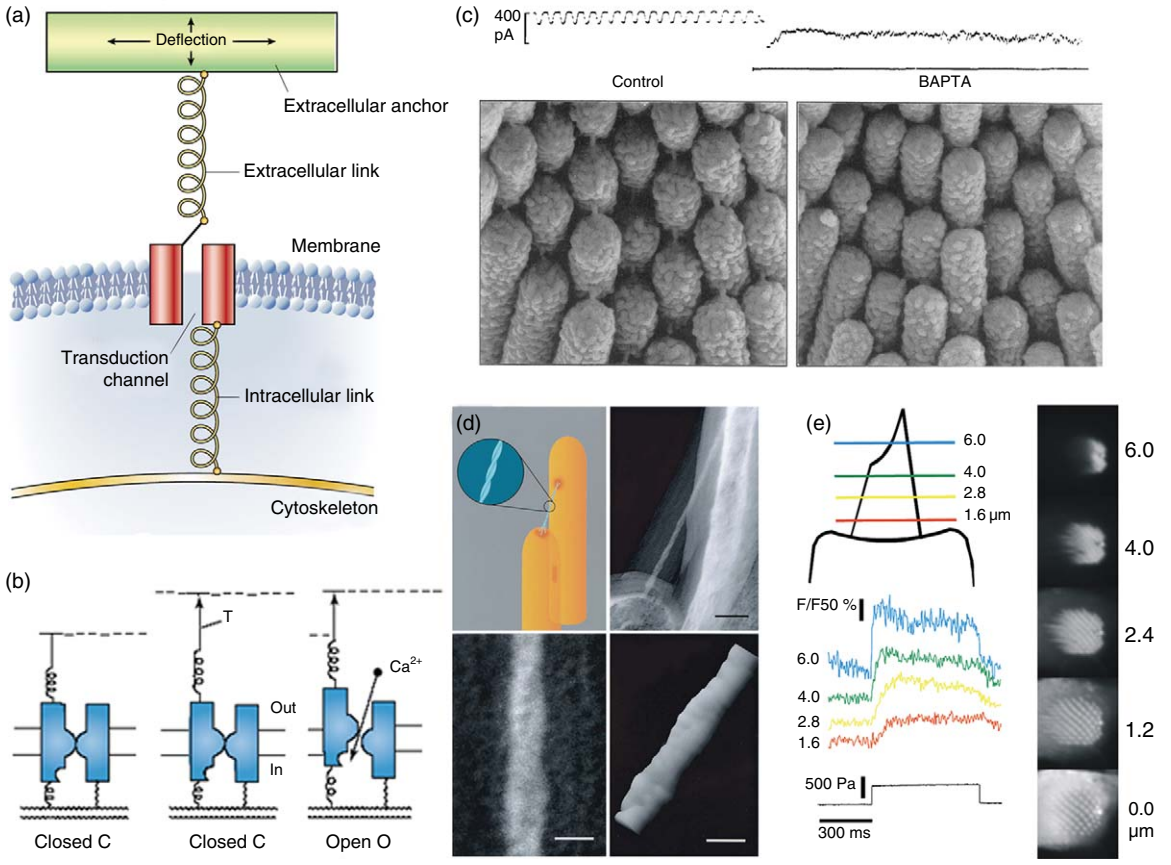

Figure 3 Tip link and gating spring. (a) Direct activation of mechanotransduction channels. A schematic diagram of a mechanosensitive channel that is gated by tension exerted perpendicular to the membrane. Deflection of a hair bundle increases tension across the membrane which directly opens the transduction channel. (b) According to the model for hair cell mechanotransduction, the channel can be found in three different states: closed with no tension on the gating spring (left), closed with the gating spring tensed (middle), and opened (right). (c) Sensitivity of mechanotransduction and tip links to calcium chelation. Transduction currents recorded from a frog saccular hair cell during sinusoidal mechanical stimulation of the bundle; when an extracellular solution containing the calcium chelator BAPTA was applied, the current was completely abolished (top panel). Scanning electron micrographs (lower panels) show frog saccular hair bundles before (left) and after (right) BAPTA treatment. Note the absence of tip links following BAPTA treatment. (d) High-resolution images of tip links from guinea pig cochlear hair cells. The top left panel shows a schematic diagram of tip link structure. Two helically intertwined protofilaments (Inset) are attached at two points to the taller stereocilium and contact three filaments emanating from the shorter stereocilium. The bottom left and top right panels are rapid-freeze deep-etched scanning electron micrographs showing a tip link visualized at different magnifications. The double coiled structure is apparent in the three dimensional reconstruction in the bottom right panel. Scale bars = 50 nm (top right), 10 nm (bottom left, right). (e) The transduction channel is located at the tips of stereocilia. A schematic diagram of a bullfrog saccular hair bundle (top left) indicates the focal plane of images shown at the right. The relative calcium concentration was monitored by the use of a fluorescent calcium indicator and two-photon scanning laser microscopy (lower left). When the bundle was stimulated by a fluid jet, the fluorescence intensity increased first at the tip of the bundle (bottom left) and then diffused to the rest of stereocilia. (a) From Gillespie, P. G. and Walker, R. G. 2001. Molecular basis of mechanosensory transduction. Nature 413, 194–202. (b) Adapted from Fettiplace, R. and Ricci, A. J. 2003. Adaptation in auditory hair cells. Curr. Opin. Neurobiol. 13, 446–451. (c) Reprinted from Assad, J. A., Shepherd, G. M., and Corey, D. P. 1991. Tip-link integrity and mechanical transduction in vertebrate hair cells. Neuron 7, 985–994. (d) Kachar, B., Parakkal, M., Kurc, M., Zhao, Y., and Gillespie, P. G. 2000. High-resolution structure of hair-cell tip links. Proc. Natl. Acad. Sci. U. S. A. 97, 13336–13341. (e) Reprinted from Denk, W., Holt, J. R., Shepherd, G. M., and Corey, D. P. 1995. Calcium imaging of single stereocilia in hair cells: localization of transduction channels at both ends of tip links. Neuron 15, 1311–1321.

relax forward (in the positive direction) by an average distance of 133 nm (Assad, J. A. *et al.*, 1991).

In a technical tour de force, Kachar B. *et al.* (2000) examined the hair cell tip link structure at high resolution by using rapid-freeze, deep-etch electron microscopy (Figure 3(d)). The authors determined that the tip link is a right-handed, periodic, coiled double filament that is 8–11 nm wide and 150–200 nm

long. The structure suggests that it is either a single wound polymer, or a pair of braided filamentous molecules, and is therefore likely to be relatively stiff and inextensible. These properties are inconsistent with the biophysical properties of the compliant transduction channel gating spring. The tip link branches at the upper end, attaching at two points to the insertional (side) plaque of the taller stereocilium. At the lower end, it seems to extend three filaments into the tip plaque. It is difficult to resolve the three filaments at the lower insertion point, but freeze–fracture images of stereociliary tips show three indentations likely left by the tip link insertions. Freeze–etch images and transmission electron micrographs of both stretched and compressed tip links were examined. A tenting phenomenon could be seen in the lower insertion of a tensioned tip link, as if the tip link is pulling the membrane away from the tip plaque, possibly straining some internal element below the membrane. A compressed tip link does not cause membrane tenting. The upper insertion point appears to remain rigid in both cases. Kachar B. *et al.* (2000) hypothesized that the tip link is not the gating spring, but that perhaps the gating spring is located elsewhere in series with the mechanotransduction apparatus. Elastic intracellular filaments at the lower end of the tip link could be components of the gating spring.

Although tip links were localized to the tips of stereocilia there was little direct evidence to suggest that this was also the site of transduction. Some investigators supported the idea that the channels were located along the latereral aspects of the stereocilia (Hackney, C. M. and Furness, D. N., 1995) or at the base of the hair bundle where the stereocilia insert into the cuticular plate (Ohmori, H. 1988).

Later studies, however, confirmed the hypothesis that the transduction channels are located at the tips of the stereocilia, imparting credence to the tip link's role in hair cell transduction. In one experiment, a transduction channel blocker was iontophoretically applied at various localized points along the hair bundle. The blocker was most effective when applied to the tips of the stereocilia, but had little or no effect when applied at the base of the bundle (Jaramillo, F., and Hudspeth, A. J., 1991). In a separate series of experiments, Denk W. *et al.* (1995) took advantage of the calcium permeability of the transduction channel and used two-photon laser-scanning microscopy, along with a fluorescent calcium indicator, to localize calcium entry in individual stereocilia. Upon positive bundle deflections, the calcium signal rose first at the tips of the stereocilia, and later in the bases, confirming that the transduction channels are located at the tips of the stereocilia (Figure 3(e)). Furthermore, calcium signals in individual stereocilia could be resolved in the two-photon imaging experiments, and the authors concluded that the transduction channels could be located at either end of the tips links (Denk, W. *et al.*, 1995). Interestingly, since transduction channels can be located at either end of the tip links, the asymmetric structure of the tip link suggests that the transduction channel is differently coupled to the tip link at each end (Kachar, B. *et al.*, 2000).

3.16.6 Adaptation

Sensory adaptation is defined as the decrease in a sensory response over time in the presence of a constant stimulus (Eatock, R. A. *et al.*, 1987) (Figure 4(a)). During and after adaptation, the full range of sensory response can still be evoked, a property that distinguishes adaptation from desensitization or inactivation. In hair cells, a large positive bundle displacement increases the open probability of the transduction channels to nearly 100%. If the bundle is held in that position, the transduction current decays over the subsequent 1–100 ms, as the transduction channels close (Figure 4(b)). However, even larger positive bundle displacements can reopen the channels that were closed by the adaptation process. Conversely, when the bundle is deflected in the negative direction, the 10% P_o at rest drops to near zero. In this case adaptation returns P_o back toward the resting level. This is particularly evident at the end of a negative step when the bundle is returned to the rest position. A rebound current is evoked before the cell adapts back the resting level. Hair cells exhibit two types of adaptation, termed slow and fast adaptation (Figure 4(c)). Slow and fast adaptation occur on different timescales, but both are regulated by calcium. Slow adaptation occurs over 10 to −100s of milliseconds and is thought to be mediated by a molecular motor, while fast adaptation occurs within a few milliseconds and is thought to result from either an inherent property of the transduction channel itself or from an associated accessory protein. Both types of adaptation shift the $I(X)$ curve in the direction of the applied stimulus (Figure 4(b), bottom panel). The shift may function to reset the operating range of the hair cell during either a positive or negative stimulus (Eatock, R. A., 2000). In vestibular hair cells, for example, the adaptation process allows the cells to remain responsive to stimuli in the presence of gravity, which exerts a relatively large tonic force on

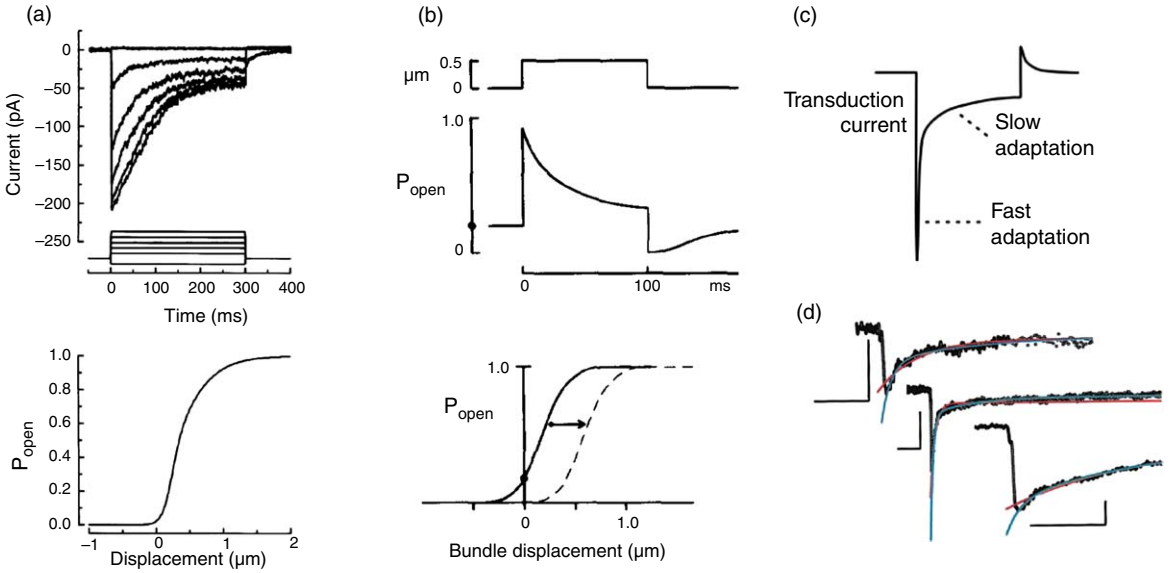

Figure 4 Hair cell adaptation. (a) A family of transduction currents from a mouse utricle hair cell evoked by the step displacements shown below. Note the decrease in current amplitude over time (due to adaptation) while the bundle is held in a fixed position. The peak current amplitude is plotted as a function of bundle displacement (bottom panel). (b) A bundle displacement increases gating-spring tension and channel open probability. Over the subsequent tens of milliseconds, adaptation proceeds and open probability declines (upper panels). Channel closure results from a shift of the sensitivity curve in the direction of the displacement (bottom panel), which suggests an adjustment of tension on channels. (c) A schematic diagram that highlights the different kinetics of fast and slow adaptation. Fast adaptation occurs within the first few milliseconds while slow adaptation follows over the subsequent tens to hundreds of milliseconds. (d) Separation of fast and slow adaptation. Mechanotransduction currents from frog sacculular hair cells fitted with single (red lines) and double (cyan) exponential curves. The data are best fit with a double exponential with time constant differing by an order of magnitude; scale bar 5 ms, 50 pA. the hair bundles. Adaptation is not complete, as approximately 20–40% of the response remains after adaptation has reached steady state, which may serve to signal tonic stimulation.

Both types of adaptation may coexist to varying degrees among auditory and vestibular hair cells and amongst various species (Wu, Y. C. *et al.*, 1999; Eatock, R. O., 2000; Holt, J. R. and Corey, D. P., 2000). It is not entirely clear whether all hair cells possess both slow and fast adaptation. The type of stimulus used to deflect the hair bundle (stiff probe or fluid jet) and the speed, or rise time, of that stimulus can affect whether fast adaptation is observed or not (Vollrath, M. A. and Eatock, R. A., 2003). A stimulus that has a slow rise time can mask the appearance of fast adaptation. It is also sometimes difficult to separate the two processes (Figure 4(d)). In mouse utricular hair cells, slow adaptation is prominent, although fast adaptation has been observed (Holt, J. R. *et al.*, 2002; Vollrath, M. A. and Eatock, R. A., 2003; Stauffer, E. A. *et al.*, 2005). In frog saccular hair cells, fast adaptation is both faster and more prominent than in mouse vestibular hair cells (Vollrath, M. A. and Eatock, R. A., 2003). Although this chapter focuses on mechanotransduction and adaptation of the hair cell transduction process itself, it is important to note that additional factors may also contribute to adaptation in the inner ear, including voltage-dependent conductances in the hair cell, and the modulation of neurotransmitter release in the afferent neuron (Eatock, R. A., 2000).

3.16.6.1 The Mechanism of Slow Adaptation

Eatock R. A. *et al.* (1987) determined that adaptation involves a decrease in current entering through the transduction channel over time. Secondly, they found that adaptation involved a shift of the $I(X)$ relationship

along the displacement axis, in the direction of the applied stimulus. Slow adaptation allows hair cells to possess both high sensitivity and a broad operating range.

Eatock R. A. *et al.* (1987) revealed several important characteristics of hair cell adaptation. First, the $I(X)$ adaptive shift occurs in response to both negative and positive displacement stimuli. But, the rate of shift is nonlinear, as it occurs faster for positive displacements than for negative displacements. Second, the shift is dependent on the extracellular calcium concentration, and both the initial rate and the final extent of the adaptive shift increase upon increasing the calcium concentration. Third, the rate of shift is temperature dependent. Fourth, the extent of the adaptive shift to more negative displacements increases even after mechanotransduction has saturated. In other words, the amount of adaptation varies with displacement amplitude even if the amplitude of the current is constant (Eatock, R. A. *et al.*, 1987). All of these characteristics suggest that hair cell mechanotransducer adaptation is an active process.

Additional experiments suggested that hair cell adaptation involves a mechanical adjustment of the tension on the gating springs of the transduction channels. When Howard J. and Hudspeth A. J. (1987; 1988) displaced hair bundles in the positive direction with a flexible glass probe, a decrease in bundle stiffness occurred with a similar time course to the simultaneously measured adaptive decline in transduction current. The mechanical relaxation of the hair bundle in the positive direction was correlated with the polarity and direction of adaptation (Figure 5(a)). Furthermore, the mechanical adjustment during adaptation is thought to involve a movement of the gating spring. The $I(X)$ curve shifted along the displacement axis during adaptation, but the slope of the curve did not change substantially (Figure 5(b)). Howard J. and Hudspeth A. J. (1988) went on to show that the relationship between bundle stiffness and displacement also shifted along the displacement axis by the same amount (Figure 5(c)). The parallel shift in the two curves without changes in slope suggested that the attachment point of the gating spring actually moves during adaptation (Hacohen, N. *et al.*, 1989), perhaps slipping down the side of the taller stereocilia to relieve tip-link tension and allowing the channels to close (Figure 5(d)).

Calcium entering the stereocilia is additionally integral to the adaptation process. Lowering extracellular

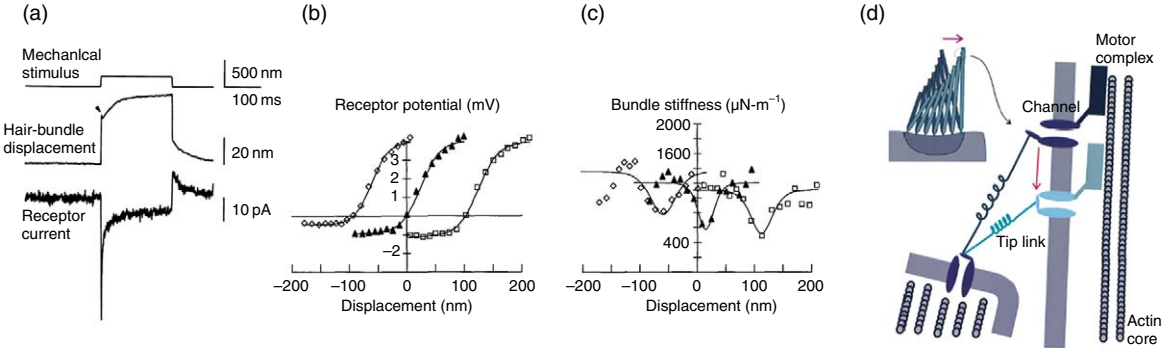

Figure 5 Bundle mechanics and slow adaptation. (a) Transduction current and bundle position were measured from a bullfrog vestibular hair cell stimulated by a force step (top panel). The force step was delivered by a flexible glass fiber of known stiffness. The bundle (middle trace) responded with an abrupt initial displacement, a twitch (arrowhead) and a slow relaxation. The current (bottom trace) revealed an initial, fast, inward transient followed by slow adaptation. The two components of adaptation in the receptor current had time courses similar to those of the mechanical relaxations. (b) As adaptation proceeds, the stimulus–response relationship shifts in the direction of the applied stimulus. (c) Hair bundle stiffness was estimated based on the amplitude of the probe displacement, the stiffness of the flexible stimulus probe, and the bundle displacement. The plot of bundle stiffness versus displacement shifted along the displacement axis parallel to the shift in the stimulus–response relationship (panel b). The dip in the stiffness-displacement curves corresponded to the midpoint of the respective stimulus–response relationships and presumably reflected a decrease in bundle stiffness due to transduction channel gating. (d) Model of slow adaptation: a motor complex in series with the channel and tip link is attach to an intracellular structure (probably the actin core): when tension is applied to the channel the motor complex releases and slips down the stereocilium which decreases gating-spring tension and allows the channel to close. (a) Howard, J. and Hudspeth, A. J. 1987. Mechanical relaxation of the hair bundle mediates adaptation in mechanoelectrical transduction by the bullfrog's saccular hair cell. Proc. Natl. Acad. Sci. U. S. A. 84, 3064–3068. (b, c) Reprinted from Howard, J. and Hudspeth, A. J. 1988. Compliance of the hair bundle associated with gating of mechanoelectrical transduction channels in the bullfrog's saccular hair cell. Neuron 1, 189–199. (d) Reprinted from Gillespie, P. G. and Corey, D. P. 1997. Myosin and adaptation by hair cells. Neuron 19, 955–958.

calcium (Eatock, R. A. *et al.*, 1987); including a high concentration of a calcium chelator in the intracellular recording solution; or depolarizing the hair cell to eliminate the entry of positively charged calcium ions during displacements (Crawford, A. C. *et al.*, 1989) all reduce the adaptation rate to positive stimuli. The rate of adaptation to negative stimuli is not dependent on extracellular calcium, however (Hacohen, N. *et al.*, 1989). These data, in sum, suggest that calcium entry into hair cell stereocilia, likely through the transduction channel itself, modulates the rate and extent of adaptation.

Finally, as alluded to earlier, slow adaptation is highly asymmetrical, with a faster rate for positive stimuli than for negative stimuli. In the positive direction, the initial rate of adaptation was found to increase linearly with the size of the displacement. The rate even increases for displacements beyond saturation, where the transduction current is at its maximum amplitude. On the other hand, the rate of adaptation for large negative displacements is nearly constant and does not depend on the size of the deflection. Large negative displacements, it is reasoned, would cause the gating spring to become slack, and allow an unloaded active adaptation element to re-tension the spring (Hacohen, N. *et al.*, 1989).

From these data, the active motor model of adaptation was developed as an extension of the gating-spring transduction model (Assad, J. A. and Corey, D. P., 1992). The active motor model involves an active force generator, or motor, which exerts a tension in the transduction channel's gating spring. During positive bundle displacements, the force generator passively slips at a rate that is dependent on displacement amplitude and calcium entry into the stereocilia (Figure 5(d)). Greater displacement amplitudes and higher concentrations of calcium increase the slipping rate. During saturating negative displacements, the unloaded motor actively tensions the gating spring by climbing, initially at a constant rate that is independent of displacement amplitude. This rate, calculated as the movement of the tip link along the stereocilium, was found to be 1–2 $\mu m\,s^{-1}$, similar to the rate of myosin moving along actin (Hacohen, N. *et al.*, 1989). After the motor senses the tension exerted by the gating spring, it slows and then stops when the channel open probability is about 10%. The open probability is determined by the opposing tensioning and slipping forces. At rest, the motor exerts a tension on the gating spring. In fact, the P_o at rest increases when extracellular calcium concentrations are decreased or the cell is depolarized to reduce calcium influx, just as decreasing extracellular calcium lowers the rate and extent of adaptation (Corey, D. P. and Hudspeth, A. J., 1983; Hacohen, N. *et al.*, 1989).

Thus, the active motor model postulates that the steady-state tension of the gating spring is set by a balance between slipping and climbing. In this model, the steady-state (i.e., at rest, or after adaptation has saturated) tension on the gating spring is adjusted by calcium, but is independent of the static position of the bundle. Also, according to this model, adaptation is complete so that the receptor current returns to the baseline value and the $I(X)$ curve shifts by an amount equal to the size of the displacement step. If the hair bundle was deflected in the positive direction by 1 μm, for example, then adaptation is predicted to cause the $I(X)$ curve to shift to the right, along the displacement axis, by 1 μm (Assad, J. A. and Corey, D. P., 1992).

However, this is not the case; adaptation is not complete. Rather, the extent of adaptation ranges between 60% and 80% of the displacement amplitude (Shepherd, G. M. and Corey, D. P., 1994; Holt, J. R. *et al.*, 1997). A 1 μm (nonsaturating) positive displacement will cause the $I(X)$ curve to shift by 0.6–0.8 μm in mouse utricular hair cells, for example, and 20–40% of the transduction current will remain at steady state, after adaptation is complete. According to the model, the movement of the upper tip link insertion point can also be calculated by multiplying the displacement of the bundle by a geometrical gain factor, gamma, that is approximately equal to the distance between the stereocilia divided by the height of the tallest stereocilium (Shepherd, G. M. and Corey, D. P., 1994). In mouse utricle hair cells, gamma is 0.047 (Holt, J. R. *et al.*, 1997), so that, at steady state, a 1 μm bundle displacement will cause the upper insertion point to slip down by about $1 \times 0.047 \times 80\% = 0.0376\,\mu m$. Shepherd G. M. and Corey D. P. (1994) added an adaptation extent spring into a revised motor model of adaptation to account for the incomplete extent of adaptation.

The original active motor model also treated the hair bundle as having no intrinsic set point, so that adaptation would occur regardless of bundle position. The hair bundle does, in reality, have a set point. In the positive direction, adaptation is essentially limitless. Larger positive stimuli increase the extent of the adaptive shift. Most hair cells are fairly resilient, but it is of course possible to damage the hair bundle with excessively large stimuli. In contrast, for large negative stimuli, the shift reaches a fixed limit. In bullfrog saccular hair cells, the fixed limit is 100–500 nm negative to the resting bundle position in 4 mM extracellular

calcium. Large negative displacements do not shift the $I(X)$ curve past this fixed limit. A negative stop was therefore added to the model to account for the negative limit (Shepherd, G. M. and Corey, D. P., 1994). The negative stop may be due to a fully extended extent spring (Yamoah, E. N. and Gillespie, P. G. 1996). Although the model for adaptation was developed for bullfrog saccular hair cells, the model applies equally well to mammalian vestibular hair cells, with minor adjustments allowed for differences in hair bundle geometry (Holt, J. R. *et al.*, 1997).

3.16.6.2 The Mechanism of Fast Adaptation

A second adaptation model, based on work with turtle auditory hair cells, posits that adaptation results as calcium enters the transduction channels and binds to an intracellular site which promotes channel closure (Crawford, A. C. *et al.*, 1991). Crawford A. C. *et al.* found that decreasing the concentration of calcium bathing turtle auditory hair cells led to a negative (leftward) shift and a decrease in the slope of the $I(X)$. The $I(X)$ shift and change in slope could be replicated by depolarizing a hair cell bathed in an extracellular solution high in calcium, suggesting that calcium is acting at an intracellular site (as depolarizing the cell toward the calcium equilibrium potential would reduce calcium influx). Note that the $I(X)$ curve actually broadens (decreases in slope), suggesting that the location of the gating spring is not climbing or slipping, as in the motor model. Rather, it was proposed that calcium, acting at an intracellular site, regulates the intrinsic open probability of the transduction channel by stabilizing one of its closed states (Crawford, A. C. *et al.*, 1991). Calcium influx therefore decreases the open probability of the transduction channel, leading to a fast decrease in transduction current amplitude during a sustained hair bundle displacement. This process was later named fast adaptation, to distinguish it from the slower active motor process. The intracellular fast adaptation sensor is unknown, but may be a calcium sensitive protein, such as calmodulin, associated with the transduction complex. Alternatively, a myosin motor may be involved in fast adaptation.

Although initially at odds, both the active motor model and the fast adaptation model seem to be valid. Each describes a physiologically distinct component of adaptation occurring on different timescales. Furthermore, they can coexist in the same hair cell, and both are calcium sensitive. Fast adaptation dominates in auditory hair cells of the turtle and rat, while slow adaptation is more prominent in vestibular hair cells of the bullfrog and mouse. The relative contribution of the two types of adaptation may depend on the frequency to which a particular type of hair cell is sensitive. In general, auditory hair cells encode higher frequencies than vestibular hair cells and thus are dominated by fast adaptation. The two components of adaptation are apparent in the adaptive decay in current amplitude in many hair cells and can be fit by a double exponential equation with fast and slow time constants. The fast time constant is usually below 5 ms, and the slower time constant is between 10 and 100 ms (Figure 4(c)) (Holt, J. R. *et al.*, 1997; 2002; Wu, Y. C. *et al.*, 1999). Rat outer hair cells exhibit fast adaptation time constants as fast as 100 μs (Kennedy, H. J. *et al.*, 2003).

Since fast adaptation can occur on a submillisecond timescale it is too fast for a system that requires the ATPase cycle of any known motor protein. While slow adaptation can be inhibited by dialyzing the hair cell with high concentrations of adenine nucleoside diphosphates and ATPase inhibitors, fast adaptation is not affected by ATPase inhibitors (Wu, Y. C. *et al.*, 1999; Holt, J. R. and Corey, D. P., 2000). Furthermore, unlike slow adaptation, the fast component of adaptation has a similar time constant for both positive and negative stimuli, suggesting that it is reversible (Wu, Y. C. *et al.*, 1999). Wu Y. C. *et al.* (1999) modeled adaptation by a scheme in which calcium ions enter through the transduction channels and act on two independent intracellular sites to modulate the activity of the fast and slow adaptation mechanisms. The initial model proposed for fast adaptation, now referred to as the channel re-closure model, suggested that calcium entry through open transduction channels alters the relationship between gating-spring tension and channel open probability such that greater tension is required to achieve the same open probability (Howard, J. and Hudspeth, A. J., 1988). In other words, with positive bundle deflections, channels open and allow calcium to enter; intracellular calcium in turn binds to a site on or near the channel. Although gating-spring tension remains, the fast adaptation mechanism causes rapid channel closure and thus a rapid decline in P_o and transduction current amplitude.

An alternate model, known as the release model, has recently been proposed (Bozovic, D. and Hudspeth, A. J., 2003; Martin, P. *et al.*, 2003; Stauffer, E. A. *et al.*, 2005; LeMasurier, M. and Gillespie, P. G., 2005). This model suggests that, following a bundle deflection, an element in series with the transduction apparatus releases tension which allows the transduction channels to

close. There are a couple of noteworthy differences between the two models. First, while the channel re-closure model suggests a fundamental change in the relationship between P_o and gating-spring tension, the release model suggests that this relationship remains constant. The re-closure model predicts that an unconstrained bundle deflected by a constant force will kick back in the negative direction (i.e., toward the shortest stereocilia) as fast adaptation proceeds (Figure 6(a), top panel). The amount of the negative movement depends on the extent of fast adaptation and the swing of the transduction channel gate. Conversely,

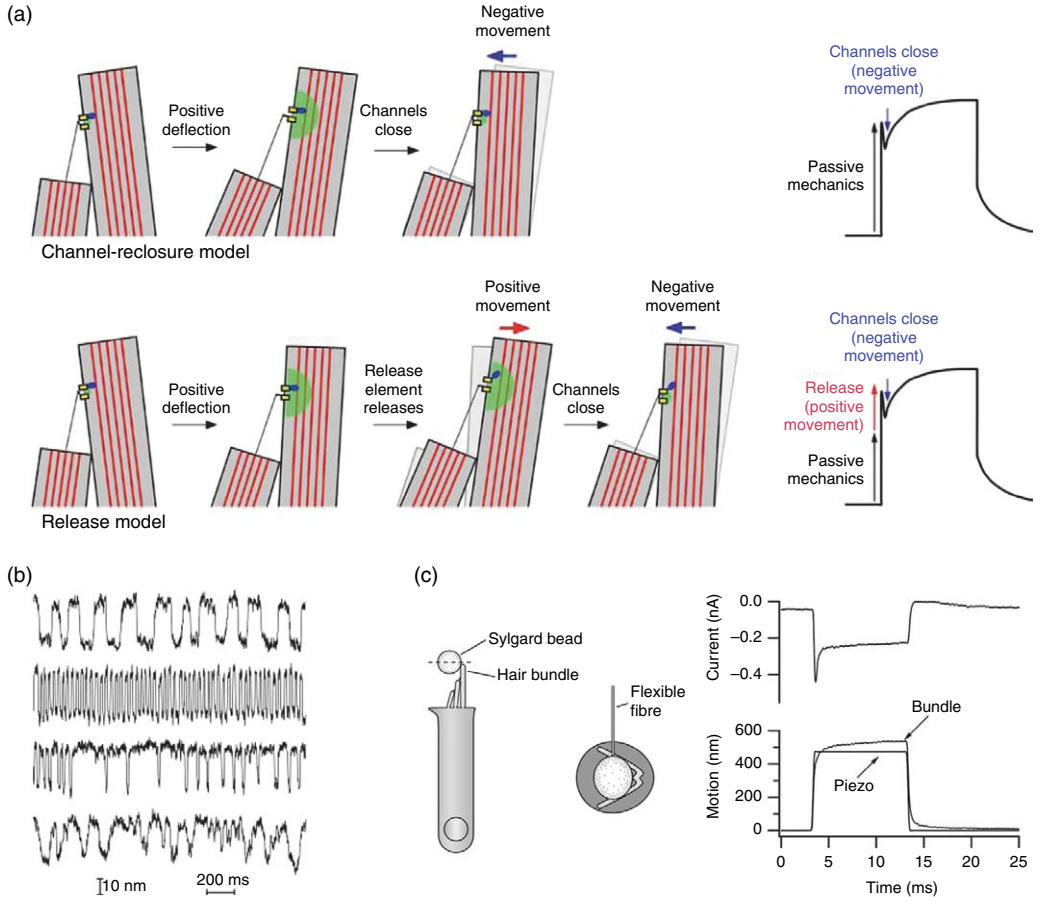

Figure 6 Fast adaptation and active hair bundle movements. (a) The cartoons present different scenarios for active hair bundle movements according to the channel reclosure model (top panel) and the release model (bottom panel). For both models, a positive deflection of the hair cell bundle causes transduction channels to open and allows Ca^{2+} to enter. In the channel reclosure model, Ca^{2+} binds to the transduction apparatus and forces the channel closed. Channel closure increases tension and moves the bundle back in the negative direction (top right). According to the release model, Ca^{2+} binding relieves tension within transduction apparatus by causing the release of an element in series. Thus, the bundle moves farther in the positive direction. The reduction in tension will subsequently allow the channel to close and rock the bundle back in the negative direction (bottom right). (b) Active bundle movements in a frog vestibular hair cell. The traces represent the spontaneous movement of saccular bundles, monitored by projecting the image of a flexible glass fiber attached to the bundle onto a pair of photodiodes. The tissue was bathed with an endolymph-like solution on the apical surface and a perilymph-like solution on the basolateral aspect. Spontaneous oscillations varied among cells from frequencies between 5 and 50 Hz with an average amplitude of 25 nm. (c) Active hair bundle movements in cochlear outer hair cells. The cartoon (left) shows the stimulus method for deflection of neonatal rat auditory hair bundles with a flexible fiber. The motion of the fiber and that of the bundle are shown at the bottom right. Interestingly, the bundle moved farther than the fiber, which indicates an active force generation. The transduction current recorded shows that the positive bundle movement paralleled fast adaptation (top right). (a) Reprinted from LeMasurier, M. and Gillespie, P. G. 2005. Hair-cell mechanotransduction and cochlear amplification. Neuron 48, 403–415. (b) Martin, P., Bozovic, D., Choe, Y., and Hudspeth, A. J. 2003. Force generation by mammalian hair bundles supports a role in cochlear amplification. Nature 433, 880–883.

the release model suggests that an unconstrained bundle will swing further in the positive direction (Figure 6(a), bottom panel). As fast adaptation proceeds, the release of tension will allow a constant force to deflect the bundle even further. Second, the two models make different predictions for the effect of fast adaptation on slow adaptation. Since both fast and slow adaptations involve mechanical adjustments in series within the transduction apparatus they are intimately related. The channel re-closure model predicts that as fast adaptation proceeds, channel re-closure will increase tension within the transduction apparatus which will, in turn, increase the mechanical drive to slow adaptation. The release model, on the other hand, reduces tension as fast adaptation proceeds and thus is predicted to reduce the drive for slow adaptation. There is experimental evidence that supports both models for fast adaptation but the mechanism of fast adaptation remains unresolved.

In an elegant series of experiments, Cheung E. L. and Corey D. P. (2006) used a laser trap to deflect bullfrog vestibular hair bundles and measure the instantaneous forces applied to and produced by the hair bundle, which allowed them to resolve nanometer scale hair bundle movements. At the same time they developed a transduction model and simulated the effect of Ca^{2+} binding at different sites in the transduction complex. Their data were best fit with a fast adaptation model in which Ca^{2+} that entered the cell via the transduction channel reduced the P_o of the channel directly and caused an increase in gating-spring tension. A theoretical consequence of this effect is the movement of the bundle in the negative direction, which correlated with the bundle twitch documented by their data and by previous experiments (Benser, M. E. *et al.* 1996; Ricci, A. J. *et al.*, 2000).

Conversely, Stauffer E. A. *et al.* (2005) found evidence that supported the release theory for fast adaptation. They recorded transduction and adaptation from both frog and mouse vestibular hair cells and used the inferred shift method (Shepherd, G. M. and Corey, D. P., 1994) to translate the adaptive decay in the transduction current into the corresponding shift of the $I(X)$ relationship. By plotting the $I(X)$ shift as a function of time and fitting with a double-exponential equation, they were able to accurately distinguish the slow and fast components of adaptation evoked by different amplitude bundle deflections. They found that the drive for slow adaptation was greatly reduced over the narrow displacement range in which fast adaptation produced near-complete adaptation. Importantly they noted that the extent of slow adaptation was inversely proportional to that of fast adaptation. Both findings were consistent with the release model for fast adaptation but inconsistent with the channel re-closure model.

Although seemingly at odds, the Stauffer G. M. *et al.* (2005) and Cheung E. L. and Corey D. P. (2006) findings indicate that both the re-closure and release mechanisms may participate in fast adaptation in the same hair cell. Certainly it remains possible that the different techniques for hair bundle stimulation, displacement-clamp versus force-clamp, could highlight one fast adaptation mechanism more than the other.

3.16.7 Active Hair Bundle Movements

Both the slow and fast adaptation models predict that the adaptation mechanisms can exert active forces on the hair bundle, albeit on different timescales. These forces can evoke hair bundle movements which may provide feedback within the cochlea to amplify the motion of the basilar membrane. How the interplay between channel gating and the fast and slow adaptation mechanisms conspire to amplify bundle motion in the cochlea is an area of intensive and fruitful research. The observation that experimental depolarization can cause an unconstrained hair bundle to move in the negative direction was consistent with the motor model for slow adaptation (Assad, J. A. and Corey, D. P., 1992). The movement is thought to result from a reduction in the driving force on calcium during depolarization. A reduction in calcium entry at the adaptation motor in turn causes the $I(X)$ curve to shift in the negative direction. According to the active motor model, the leftward shift of the $I(X)$ results from an increase in the tension exerted on the transduction channel gating spring by a climbing motor. The model predicts that the increase in gating-spring tension will cause the hair bundle to pivot in the negative direction. Indeed, the hair bundle moves in the negative direction upon depolarization, and both the movement and $I(X)$ shift are abolished by reducing extracellular calcium or by application of transduction channel blockers (Assad, J. A. and Corey, D. P., 1992).

Fast adaptation has additionally been linked to the generation of active hair bundle forces, and with a speed that may allow it to contribute to amplification at the high frequencies to which cochlear hair cells are sensitive. During excitatory hair bundle displacements

with a flexible glass probe, turtle auditory hair cells were found to initially move in the positive direction, followed by rapid recoil in the negative direction. The positive movement is most likely due to the increase in gating compliance of the bundle as the transduction channels open. The recoil movement of the hair bundle, detected using a sensitive photodiode, followed the same time course of fast adaptation, had a similar calcium dependence as fast adaptation and was abolished by blocking the transduction channels. The negative bundle movement is therefore most likely caused by the fast adaptation process (Ricci, A. J. *et al*., 2000).

However, Benser M. E. *et al.* (1996) proposed an alternative mechanism to account for the initial positive bundle movement and subsequent recoil in the negative direction. The authors suggest that movements of the adaptation motors could provide a rapid decrease, followed by an increase, in gating-spring tension. In response to a positive stimulus (or to calcium), the adaptation motor could tilt, or rock backwards thereby causing a reduction in gating-spring tension. The reduced tension would allow the bundle to move in the positive direction. Subsequently, a single power stroke by the adaptation motors would increase the gating-spring tension, thereby pulling the bundle back in the negative direction. This model predicts that gating-spring tension should increase as the motors pull the bundle in the negative direction, thereby keeping the transduction channels open (Benser, M. E. *et al*., 1996).

The results of Kennedy H. J. *et al.* (2005) lend support to the model proposed by Benser M. E. *et al.* (1996). Using flexible glass fibers to displace bundles and measure the resulting forces, Kennedy H. J. *et al.* (2005) demonstrated that hair bundles of mammalian outer hair cells can produce force on a submillisecond timescale. The time course of force production was found to correlate with fast adaptation in these cells. Interestingly, force was generated in the positive direction during a positive displacement (Figure 6(c)). Therefore, the hair bundle actually moves further in the direction of the applied stimulus (Kennedy, F. J. *et al*., 2005). The authors suggest that an element in series with the transduction channel gate may rock in place during fast adaptation, thereby relieving tension and allowing the bundle to move further in the positive direction (Kennedy, F. J. *et al*., 2005). The identity of this putative element is currently unknown. Although the ATPase cycle of a myosin is too slow to account for this fast (<1 ms) force generation by outer hair cells, internal conformational changes within a myosin molecule to produce the rocking motion suggested by Benser M. E. *et al.* (1996) could presumably occur on a much faster timescale. As such, the model proposed by Benser M. E. *et al.* (1996) is still entirely feasible.

On the other hand, as previously mentioned, fast adaptation is associated with a bundle movement, or recoil, in a direction opposite that of the applied stimulus in turtle auditory hair cells. It is unclear why turtle hair cells exhibit fast adaptation-associated movements in a direction opposite to that of mammalian outer hair cells. The results of Ricci A. J. *et al.* (2000) suggest that the transduction channels actually close during the fast adaptation process in turtle hair cells, as the negative bundle movement appears to temporally coincide with the rapid closure of the transduction channels due to fast adaptation. The model proposed by Benser M. E. *et al.* (1996), however, suggests that the channels will remain open as the motor pulls the bundle in the negative direction, keeping tension on the gating spring. How can these results be reconciled? Turtle and mammalian auditory hair cells may simply utilize different fast adaptation mechanisms. Alternatively, both processes may occur simultaneously, or at different phases of a waveform stimulus.

The adaptation process can also cause the hair bundle to spontaneously oscillate in the absence of stimulation. Bullfrog saccular hair cells were placed in a chamber that separates the basolateral surfaces of the cells from the apical hair bundles, in order to replicate the *in vivo* ionic environment. When the hair bundles were perfused with an endolymph-like low calcium solution, and the basolateral cell bodies placed in a perilymph-like solution, the hair bundles were found to exhibit spontaneous oscillations at frequencies of 5–50 Hz (Figure 6(b)). Transduction channel blockers inhibited the oscillations and drugs that affect myosins altered their rate. Increasing calcium made the oscillations faster and smaller in amplitude, while decreasing calcium had the opposite effect. The oscillations, which still occur in a voltage-clamped cell, are therefore thought to result from the interaction of the transduction channel gating compliance with the calcium-dependent activity of the adaptation motor (Martin, P. *et al*., 2003). It is currently unknown whether mammalian vestibular or auditory hair bundles oscillate spontaneously *in vivo*.

The fast adaptation process could, in principle, cause an auditory hair cell's bundle to oscillate at

much higher frequencies than those found in bullfrog saccular hair cells. Turtle auditory hair cells can exhibit calcium-dependent oscillations at higher frequencies upon the sustained application of a bundle displacement (Ricci, A. J. *et al.*, 1998). Conceptually, one can imagine a sine-wave stimulus with a frequency that matches the innate resonant frequency of the cell impinging upon the hair bundle. When the hair bundle is deflected in the positive direction, during the positive phase of the stimulus, the increase in gating-spring compliance as the transduction channels open will act in a positive feedback manner to enhance hair bundle movement. Alternatively, according to the model proposed by Benser M. E. *et al.* (1996), the rocking of a myosin to reduce gating-spring tension will enhance bundle movement in the positive direction. Fast adaptation will ensue and lead to channel closure and reset the tension in the gating spring. If channel closure coincides with the negative-going phase of bundle displacement, the movement in the negative direction will also be enhanced. When the channels are closed, the calcium concentration at the intracellular fast adaptation sensor rapidly drops (due to calcium buffering, diffusion, and the operation of calcium ATPases), allowing the channel to open once again, and the process to be repeated. The mechanical forces exerted by the hair bundle, driven by fast adaptation, may therefore amplify the auditory stimulus, particularly at frequencies that match the characteristic frequency of the hair cell. Fast adaptation may therefore both amplify and tune the hair cell's response to a specific stimulus frequency.

Finally, the fast and slow adaptation processes may actually combine to produce oscillations at a frequency specific for the stimuli detected by the cell. The specific frequency and amplitude of the oscillations would be affected by the rates of slow and fast adaptation, hair bundle geometry, the number of functional transduction channels, the amount of calcium that enters the transduction channels, external calcium concentration, and intracellular calcium dynamics, among other things. As a side note, spontaneous otoacoustic emissions, the spontaneous production of sounds by the ear, are thought to result from active mechanical processes within the ear, possibly including hair bundle oscillations that result from the adaptation process (Jaramillo, F. *et al.*, 1993; Martin, P. *et al.*, 2003).

Slow and fast adaptation play important roles in hair cell mechanosensory transduction. First, slow adaptation allows hair cells to respond to phasic stimuli in the presence of tonic stimuli that would otherwise saturate the hair cell's response. Second, adaptation may function to tune and amplify the responses of auditory and vestibular hair cells. Third, adaptation serves to maximize the sensitivity of both auditory and vestibular hair cells by exerting a resting tension on the spring that gates the transduction channel. The tension exerted by the adaptation motor moves the resting position of the hair cell into the steep portion of the $I(X)$ curve, where it is most sensitive to hair bundle displacements. Fourth, a slipping adaptation motor may protect the integrity of the mechanotransduction apparatus. During large positive displacements, the motor slips to relieve tension in the gating spring. If the motor did not slip, excessive tension placed on the gating spring could conceivably break or irreversibly damage the transduction apparatus. Fifth, the adaptation motor may play a pivotal role in the assembly of the mechanotransduction apparatus by shuttling it along the actin filaments to the tips of the stereocilia (Zhao, Y. *et al.*, 1996; Géléoc, G. S. and Holt, J. R. 2003a; Gillespie, P. G. and Cyr, J. L. 2004).

To summarize, the biophysical model of mechanosensory transduction in hair cells postulates that an elastic gating spring directly opens mechanosensitive transduction channels located at stereociliary tips. Tip links are necessary for functional mechanotransduction, and their location and orientation suggest that they may function to gate the transduction channel. The motor model of adaptation, an extension of the gating-spring model, hypothesizes that a force generator, or molecular motor, exerts a resting tension on the gating spring. The motor can passively slip to relieve tension on the gating spring, and actively climb to increase tension in the gating spring. One fast adaptation theory proposes that calcium directly binds to an intracellular site and decreases the open probability of the transduction channel, while the other suggests that calcium promotes release of tension from an intracellular element which allows the channel to close. The biophysical model has provided a framework in which to examine the molecular components of the mechanotransduction and adaptation apparatus. The elements within the model, including the transduction channel, adaptation motor, elastic gating spring, adaptation extent spring, negative stop, the tip link, and the fast adaptation site are all amenable to molecular identification. Once identified, various tenets of the biophysical model can be further tested.

3.16.8 Molecular Identification

3.16.8.1 Slow Adaptation and Myosin-Ic

Slow adaptation is thought to be mediated by a molecular motor. Since hair cell stereocilia contain actin filaments, myosin molecules are ideal candidates for the slow adaptation motor. Furthermore, the actin cores of stereocilia support myosin motility. Myosin-2 coated beads were found to move at a rate of 1–2 $\mu m\,s^{-1}$ toward the tips of the actin cores of demembranated stereocilia, which matched the predicted direction and speed of a climbing adaptation motor (Shepherd, G. M. *et al.*, 1990). In addition, slow adaptation can be inhibited by dialyzing the hair cell with high concentrations of adenine nucleoside diphosphates, which inhibit ATPases, and by myosin ATPase inhibitors (Gillespie, P. G. and Hudspeth, A. J., 1993; Yamoah, E. N. and Gillespie, P. G., 1996). These preliminary findings launched a search for hair cell myosins that might participate in adaptation. The search focused on myosins that localized to the stereocilia and on myosins with biophysical properties consistent with the putative hair cell adaptation motor.

To identify the myosin isozymes expressed by hair cells, Solc C. K. *et al.* (1994) used an RT-PCR screen and found at least ten different myosin isozymes in the bullfrog saccule, including myosin-6, 7a, 1a, 1c, 5, 10, and four myosin-2 isozymes (Solc, C. K. *et al.*, 1994). A comprehensive antibody localization study found that myosin-1c (previously known as myosin-1*beta*), VI, and VIIa are all expressed in hair cell stereocilia, among other places (Hasson, T. *et al.*, 1997). More recently, myosins IIIa and XV have been localized to the hair bundle as well (Schneider, M. E. *et al.*, 2006; Belyantseva, I. A. *et al.*, 2003). Of these, myosin-1c was localized to the tips of stereocilia, the putative location of the adaptation motor. Myosin-7a colocalized with the more basal cross-links that connect adjacent stereocilia, and myosin-6 appeared to concentrate around the stereociliary rootlets at the cuticular plate (Hasson, T. *et al.*, 1997). Myosin-15a was also localized to the tips of stereocilia (Belyantseva, I. A. *et al.*, 2003) where it seems to play a role in stereocilia elongation and myosin-3a appears to cap stereocilia tips (Schneider, M. E. *et al.*, 2006).

High-resolution quantitative immunoelectron microscopy found the highest density of myosin-1c at both ends of the tip link. The labeling was greatest 100 nm above the side-plaque, an electron-dense region along the sides of the stereocilia at the upper tip-link insertion point, and at the tip plaques, the location of the lower tip-link insertion point at the tip of the stereocilium (Figure 7(a)) (Garcia, J. A. *et al.*, 1998). The presence of myosin-1c along the side plaque is in accord with the motor model of adaptation. In this position the motor may be either directly or indirectly attached to the tip link or the transduction channel and can slip or climb along the steroeciliary actin core in response to changes in gating-spring tension. The localization of myosin-1c at the tips of the steroecilia (i.e., the lower end of a tip link) is a bit more puzzling. It is possible that it is simply involved in anchoring the mechanotransduction apparatus. A second possibility is that an unloaded myosin-1c continues to climb to the end of the actin filament after the tip link or gating spring is broken.

Based on the immunolocalization data, myosin-1c therefore became a prime candidate for the adaptation motor. Myosin-1c, a (+)-directed motor, is a ~118 kDa single-headed myosin with three domains. The N-terminal globular head domain binds actin and hydrolyzes ATP. The neck region contains four calmodulin-binding IQ (isoleucine-glutamine) domains. The C-terminal basic tail domain binds anionic (negatively charged) phospholipids, including phosphatidylserine and phosphatidylinositol-4,5-bisphosphate (Gillespie, P. G. and Cyr, J. L., 2004).

To test the putative role of myosin-1c in adaptation, a myosin-1c targeted gene deletion, or knockout, mouse was created. Unfortunately, deleting myosin-1c was found to create embryonic lethality (Holt, J. R. and Corey, D. P., 2000). Therefore, a novel, chemical-genetic strategy was developed to test the role of myosin-1c in hair cell adaptation. Gillespie P. G. *et al.* (1999) designed a missense mutation in myosin-1c, replacing tyrosine-61 with a glycine (Y61G). This mutation has minimal effects on the normal ATP hydrolytic activity and motility of myosin-1c, but was found to confer a selective sensitivity to ADP analogs modified at the N^6 position with a bulky side group. The same modified nucleotides do not affect wild-type myosin-1c, due to unfavorable interactions between tyrosine-61 and the bulky N^6 substituent (Gillespie, P. G. *et al.*, 1999).

Multiple modified ADP analogs were screened for efficacy and selectivity, and N^6(2-methyl-butyl) ADP (termed NMB-ADP) was found to be the best. Indeed, NMB-ADP potently and selectively inhibited the ATPase activity of myosin-1c. The inhibition caused Y61G myosin-1c to remain tightly bound to actin in a rigor-like state. Furthermore, NMB-ADP and Y61G myosin-1c were dominant and inhibited mixtures with

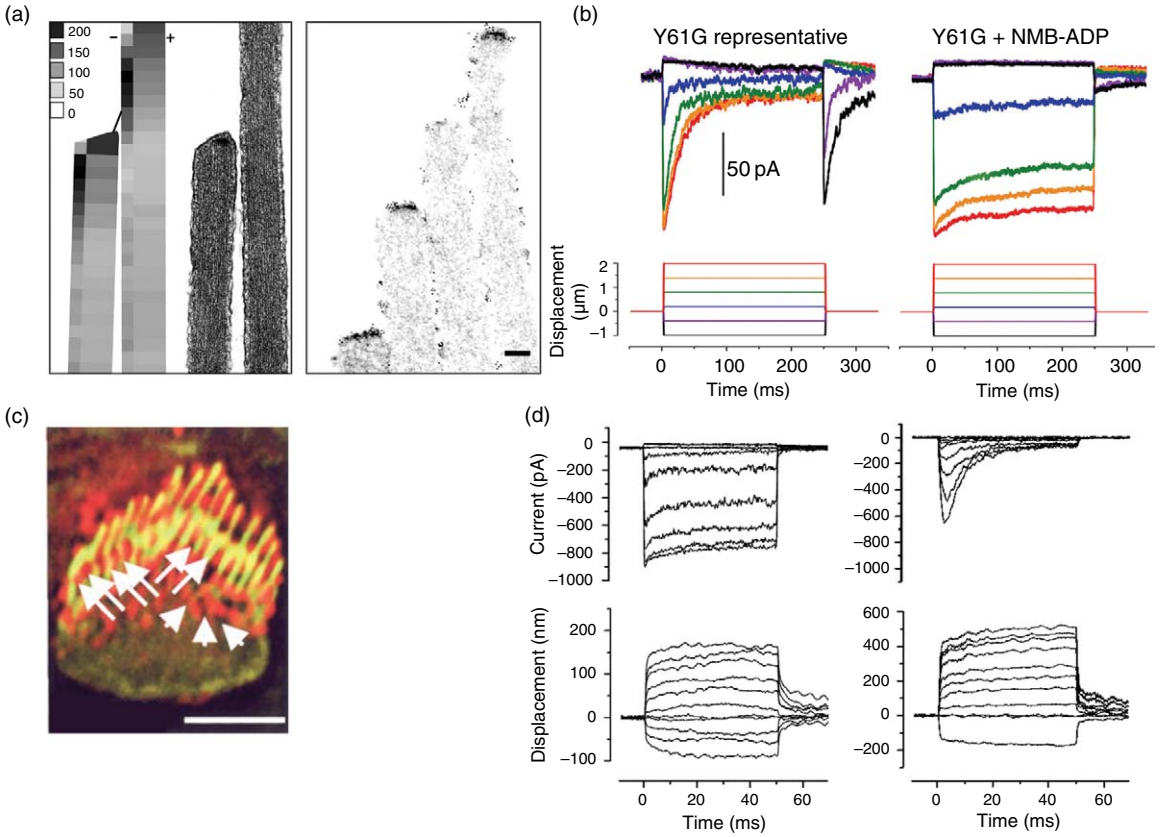

Figure 7 Myosins and adaptation. (a) Immuno-EM localizes myosin-1c to either end of the tip link in bullfrog saccular hair cells. A representative image is shown on the right. Quantification of data from multiple stereocilia is shown on the left. The intensity scale indicates immunogold particles per square micrometer; darker shading indicates an area with a higher density of particles and hence a presumably higher density of myosin-1c. (b) Myosin-1c participates in adaptation in mouse utricle hair cells. In the absence of the inhibitor, NMB-ADP, cells expressing Y61G myosin-1c exhibit normal adaptation (left). Notice the decline in current amplitude due to adaptation, as well as the rebound currents at the termination of steps in the negative direction. In contrast, inhibiting Y61G myosin-1c with NMB-ADP blocks adaptation (right). (c) Immunolocalization of myosin-7a (red) in an inner hair cell from a P5 mouse. F-actin bundles of the stereocilia are shown in green. Myosin-7a is localized toward the base of the longest stereocilia (arrows), at the cuticular plate (arrowheads), and toward tips of stereocilia. (d) A family of representative transduction currents, recorded at −84 mV, from a heterozygous myosin-7a control outer hair cell (top left) in response to a fluid-jet stimulus (bottom left). Bundle displacement at the tip of the hair bundle is indicated on the bottom left. Note that negative (inhibitory) bundle displacements turn off a small current on at rest. Homozygous myosin-7a mutant hair cells (top right) required larger bundle displacements (bottom right) to evoke transduction currents. Myosin-7a mutants also exhibited an open probability at rest of zero as well as slowed onset kinetics and a greater rate and extent of adaptation. (a) Reprinted from Garcia, J. A., Yee, A. G., Gillespie, P. G., and Corey, D. P. 1998. Localization of myosin-Ibeta near both ends of tip links in frog saccular hair cells. J. Neurosci. 18, 8637–8647. (b) Adapted from Stauffer, E. Neurosci. 5, 41–47.

wild-type myosin-1c that consisted of as little as 10% mutant myosin (Gillespie, P. G. *et al.*, 1999). With this tool in hand, Holt J. R. *et al.* (2002) created conventional transgenic mice that expressed Y61G myosin-1c as well as endogenous wild-type myosin-1c in order to examine the role of myosin-1c in vestibular hair cell adaptation.

Holt J. R. *et al.* (2002) used the whole-cell tight-seal recording technique to record transduction currents from transgenic mouse utricle hair cells while

deflecting the hair bundles with a stiff glass probe or a fluid jet. Adaptation was assayed by examining the decline in transduction current amplitude in the presence of constant bundle deflections, as well as by directly assessing the positive and negative shifts of the $I(X)$ that result from adaptation motor slipping and climbing, respectively. They found that Y61G myosin-1c expressing utricular hair cells have transduction and adaptation properties indistinguishable from wild-type in the absence of NMB-ADP. When cells were dialyzed with NMB-ADP, adaptation was normal early in the recording. However, later in the recording, after NMB-ADP was allowed to diffuse into the cell and, presumably, to the tips of the stereocilia, adaptation was blocked. NMB-ADP did not affect wild-type hair cells. The fact that NMB-ADP blocked adaptation to negative deflections, which requires an actively climbing adaptation motor, is perhaps the most convincing result. The authors concluded that myosin-1c participates in hair cell adaptation in the mouse utricle (Holt, J. R. *et al.*, 2002). These results were later confirmed using a knock-in mouse that expressed only the Y61G form of myosin-1c (Figure 7(b); Stauffer, E. A. *et al.*, 2005). Myosin-1c therefore became the first identified member of the mechanotransduction complex.

3.16.8.2 Myosin-Ic Binding Partners

These results begged the question: how and with what is myosin-1c interacting in the hair cell? Cyr J. L. *et al.* (2002) used various epitope-tagged recombinant myosin-1c fragments to identify myosin-1c binding sites within the hair cell, and to characterize the interactions of these sites with myosin-1c. Using immunohistochemistry, the authors found that myosin-1c seems to interact with unknown receptors (binding sites) at the tips of hair cell stereocilia using its calmodulin-binding IQ domains located in the neck region of the protein. Surprisingly, the tail domain is not required for these interactions to occur. It is not entirely clear which of the four IQ domains is important for binding *in vivo*. The first two IQ domains, IQ1 and IQ2, are sufficient for binding, but a calmodulin-occupied IQ3 site seems to enhance the interaction. Excess calmodulin blocks the interaction of myosin-1c with its hair cell binding partners, presumably by binding to previously unoccupied IQ domains. Finally, the fact that binding is affected by the calcium-sensitive protein calmodulin suggests that calcium may modulate interactions between the adaptation motor and other elements of the mechanotransduction apparatus (Cyr, J. L. *et al.*, 2002).

More recently, anionic membrane phospholipids, including phosphatidylinositol 4,5-bisphosphate (PIP2), were found to directly bind to the IQ domains of myosin-1c (Hirono, M. *et al.*, 2004) (although PIP2 does not seem to be the myosin-1c receptor discussed above). PIP2 localizes to the apical two-thirds of the stereocilia in some bullfrog saccular hair cells, appearing to be excluded from basal portions by the phosphatidylinositol lipid phosphatase, Ptprq. Interestingly, either blocking PIP2 synthesis or sequestering PIP2 using various drugs was found to reduce the rate of both slow and fast adaptation. Depletion of PIP2 also led to a decline in, and the eventual loss of, transduction current amplitude. PIP2 therefore seems to play an essential role in hair cell transduction and adaptation. Hirono M. *et al.* (2004) suggest that the lipid binding site within the IQ domains of myosin-1c might function to bring the calcium sensor for slow adaptation, presumed to be one of the IQ domains, closer to the stereociliary membrane, where calcium levels may be elevated. It is also possible that hair cells could vary PIP2 turnover dynamics in order to regulate transduction and adaptation (Hirono, M. *et al.*, 2004). Alternatively, PIP2 has been found to dynamically regulate the adhesive forces between actin-based cytoskeletal elements and the plasma membrane in fibroblasts (Raucher, D. *et al.*, 2000), and could function in a similar fashion at the location of the mechanotransduction complex.

3.16.8.3 Other Hair Bundle Myosins

Myosin-7a has emerged as an alternative candidate for the hair cell adaptation motor. Recessive mutations in the gene encoding myosin-7a have been linked to deafness in humans and in mice. Although myosin-7a is localized to hair cell stereocilia, it is not restricted to stereocilia tips (Figure 7(c)) (Hasson, T. *et al.*, 1997; Senften, M. *et al.*, 2006). Myosin-7a, a (+)-directed motor, contains an actin and ATP-binding head domain, and five IQ motifs in its neck domain. The tail contains two FERM (band 4.1 protein, ezrin, radixin, moesin) domains, which interact with certain cytoskeletal proteins (Inoue, A. and Ikebe, M. 2003).

Kros C. J. *et al.* (2002) examined transduction and adaptation in cochlear inner and outer hair cells of mice with myosin-7a mutations. One mutation is associated with reduced and presumably dysfunctional myosin-7a protein, while a second leads to a

very low expression level and a more severe phenotype, including disorganization of the hair bundle. The authors displaced hair bundles with a fluid jet stimulus, and recorded transduction currents (Figure 7(d)). Both myosin-7a homozygous mutants exhibited similar alterations in transduction and adaptation as compared to heterozygous controls. The resting open probability was zero in homozygotes, versus 4.8% in control. In addition, much larger than normal excitatory displacements were needed to elicit transduction currents in homozygotes. In response to a negative stimulus, the adaptation motor climbs up the stereocilium and increases tension on the gating spring. Therefore, an inward rebound current results upon returning to the resting bundle position at the termination of a negative stimulus. Controls exhibited this rebound, while homozygous mutants did not. The kinetics of transducer current activation were also slowed in the homozygous mutants. Taken together, these results suggest that the gating spring is abnormally slack in the homozygous myosin-7a mutants. Slipping adaptation evoked by positive steps was found to be faster in the homozygous mutants, and the extent of adaptation was greater as well. The authors therefore propose that myosin-7a participates in anchoring the stereociliary membrane to its actin core (possibly through its FERM domains), thereby tensioning membrane-bound elements of the transduction complex, including the channel and its gating spring, the tip link, and the adaptation extent spring (Kros, C. J. *et al.*, 2002).

Although the results of Holt J. R. *et al.* (2002) demonstrated that functional myosin-1c is crucial for adaptation, the data did not prove whether myosin-1c is the only myosin involved in the adaptation process. Locking Y61G myosin-1c onto actin in a rigor-like state apparently inhibited the motility of wild-type myosin-1c, and could similarly inhibit the motility of other myosins involved in adaptation, including myosin-7a. Also, the results of Kros C. J. *et al.* (2002) could be due to developmental effects of the myosin-7a mutation, and the immunolocalization data places myosin-7a along the entire stereocilium, not only at the ends of the tip links. Myosin-7a therefore may additionally participate in anchoring the lateral links along the sides of the stereocilia, further complicating interpretation of the data (Hasson, T. *et al.*, 1997; Kros, C. J. *et al.*, 2002). Or, myosin-7a may transport a component of the adaptation motor, but not participate in adaptation *per se*. The hair bundles of myosin-7a homozygous mutants are also structurally abnormal. Even though similar results were obtained with myosin-7a mutants that have differing severities of bundle disorganization, any disorganization at all confounds interpretation. Finally, Holt J. R. *et al.* (2002) only examined adaptation in vestibular hair cells, while Kros C. J. *et al.* (2002) only looked at auditory hair cells. It is possible that myosin-1c is the adaptation motor of vestibular hair cells, while myosin-7a serves a similar function in auditory hair cells.

Of course, it is also entirely possible that both myosins participate cooperatively as members of the mechanotransduction and adaptation apparatus. Myosin-7a may anchor the transduction complex at the opposite end of the gating spring as myosin-1c, so that myosin-7a and myosin-1c are in series. Therefore, the loss of one motor would make the other ineffective (Gillespie, P. G. 2002). Alternatively, myosin-1c and myosin-7a may interact with each other, possibly through intermediate binding partners, to affect the adaptation process. For example, PHR1, an integral membrane protein found in hair cells, has been found to interact, *in vitro*, with the tail regions of both myosin-1c and myosin-7a (Etournay, R. *et al.*, 2005). PHR1 contains a pleckstrin homology (PH) domain at its N-terminus and a transmembrane domain at its C-terminus (Xu, S. *et al.*, 2004). If PHR1 is present at the tips of stereocilia, it may participate in anchoring myosin-1c and/or myosin-7a to the cell membrane. PHR1 can apparently form homodimers, and so could conceivably interact with both myosin-1c and myosin-7a through the PH domain of each dimer (Etournay, R. *et al.*, 2005).

Myosin-7a also interacts with the cytoplasmic domain of protocadherin 15 (PCDH15), a member of the cadherin superfamily expressed in the hair cell bundle (Senften, M. *et al.*, 2006). Expression of PCDH15 is drastically reduced in stereocilia of myosin-7a deficient shaker-1 mice, whereas myosin-7a is strongly reduced in Ames waltzer^{av3j} mice, which lack PCDH15. This interaction is likely to play a role during bundle development as hair bundles of both Ames waltzer and shaker-1 mice show dramatic disorganization (Senften, M. *et al.*, 2006).

Myosin-15a is an additional hair cell myosin that could participate in adaptation (Belyantseva, I. A. *et al.*, 2003). Mutations in myosin-15a are associated with deafness in humans (DFNB3) and shaker (*Myo15*^{sh2}) mice. Myosin-15a localizes to stereocilia tips, overlapping with the barbed (+) ends of actin filaments and extending to the overlying apical plasma membrane. In deaf *Myo15*$^{sh2/sh2}$ mice, stereocilia appear to lack Myosin-15a, are abnormally short, and are nearly

equal in length (Belyantseva, I. A. *et al.*, 2003). During development, myosin-15a appears when the hair bundle begins to develop its staircase arrangement. Belyantseva I. A. *et al.* (2003) therefore proposed that myosin-15a is necessary for the staircase formation of the hair bundle. Additionally, in mature cells, the amount of myosin-15a at stereocilia tips is positively correlated with stereocilia length (Rzadzinska, A. K. *et al.*, 2004). Rzadzinksa A. K. *et al.* (2004) also suggested that myosin-15a may participate in the actin treadmilling process which serves to constantly renew and dynamically maintain stereocilia length. Due to its location near the tips of stereocilia (Rzadzinska, A. K. *et al.*, 2004), myosin-15a may also affect the tension applied to the tip links at the lower attachment points, and may therefore influence the adaptation process (Belyantseva, I. A. *et al.*, 2003). However, a recent report from Stepanyan R. *et al.* (2006) showed normal transduction and adaptation in myosin-15a deficient mice, suggesting that myosin-15a is not required for adaptation in mutant mice.

3.16.8.4 Fast Adaptation

The leading hypothesis for the mechanism of fast adaptation suggests that calcium binds directly to the transduction channel or a closely associated protein, and promotes channel reclosure. If this is indeed the case, identification of the molecular correlate of fast adaptation awaits molecular identification of the transduction channel itself (see Section 3.16.8.6).

However, there is a growing body of evidence that supports the release model for fast adaptation. In particular, a novel proposal suggests that, in addition to its role in slow adaptation, myosin-1c may be the release element that drives fast adaptation (Stauffer, E. A. *et al.*, 2005). Stauffer E. A. *et al.* (2005) used a chemical-genetic strategy similar to that used to identify the role of myosin-1c in slow adaptation (Holt, J. R. *et al.*, 2002). In this case, Stauffer E. A. *et al.* (2005) generated knock-in mice that expressed the Y61G mutation in myosin-1c instead of the wild-type form of the protein. Surprisingly, when they examined adaptation recorded from vestibular hair cells of Y61G knock-in mice with the selective inhibitor NMB-ADP in the recording pipette (Figure 7(b)), they found a significant reduction in the rates of both slow and fast adaptation. To separate the two components they used the inferred shift method (Shephred, G. M. and Corey, D. P., 1994) to analyze adaptation rates and found that NMB-ADP slowed the rate of fast adaptation by more than 80% relative to wild-type controls. This result held true for fast adaptation evoked both by positive and negative bundle deflections. The data suggested that in addition to its role in slow adaptation, which was also confirmed by these experiments, myosin-1c may also play a role in fast adaptation. Although the ATPase cycle of myosin-1c would be too slow to explain the rapid kinetics of fast adaptation, the authors hypothesized that an ATP-independent conformational change in the structure of myosin-1c may release tension within the transduction apparatus and allow transduction channels to close. The rapid release of tension would allow a constant force to deflect the hair bundle further in the positive direction. When the bundle is deflected back in the negative direction the hypothesis suggests that the decrease in tension will allow the myosin to rapidly flip back to its lower energy, resting conformation so that it is reprimed for the next cycle. Thus, myosin-1c may be a multifunctional molecule serving as the motor to drive slow adaptation, the release element to drive fast adaptation and, if the latter, perhaps a component of the cochlear amplifier as well, which serves to amplify and tune the auditory response to faint sounds. However, the role of myosin-1c in both slow and fast adaptation in cochlear hair cells has not yet been examined.

3.16.8.5 Tip Links

Nearly twenty years after the discovery of the tip link, two groups have identified cadherin-23 as a putative molecular component of the tip link (Siemens, J. *et al.*, 2004; Sollner, C. *et al.*, 2004). Cadherin-23 is a member of the large cadherin family of adhesive glycoproteins. Cadherin 23 contains an extracellular domain that consists of 27 cadherin repeats, a transmembrane domain, and a cytoplasmic domain that may be linked to the cell cytoskeleton. Cadherin repeats are independently folding motifs of around 110 amino acids that contain certain conserved sequences (Wheelock, M. J. and Johnson, K. R., 2003). Each cadherin repeat is approximately 3 nm wide and 5 nm long, and contains seven *Beta*-strands rigidly linked together by hydrogen bonds (Corey, D. P. and Sotomayor, M. 2004) (Figure 8(e)). The extracellular domains mediate the adhesive functions of cadherins in a calcium-dependent manner. Calcium binds to specific residues within the negatively charged cadherin repeat to ensure proper folding and impart rigidity to the extracellular domain (Wheelock, M. J. and Johnson, K. R., 2003). Calcium also promotes the interaction between adjacent cadherin repeats in

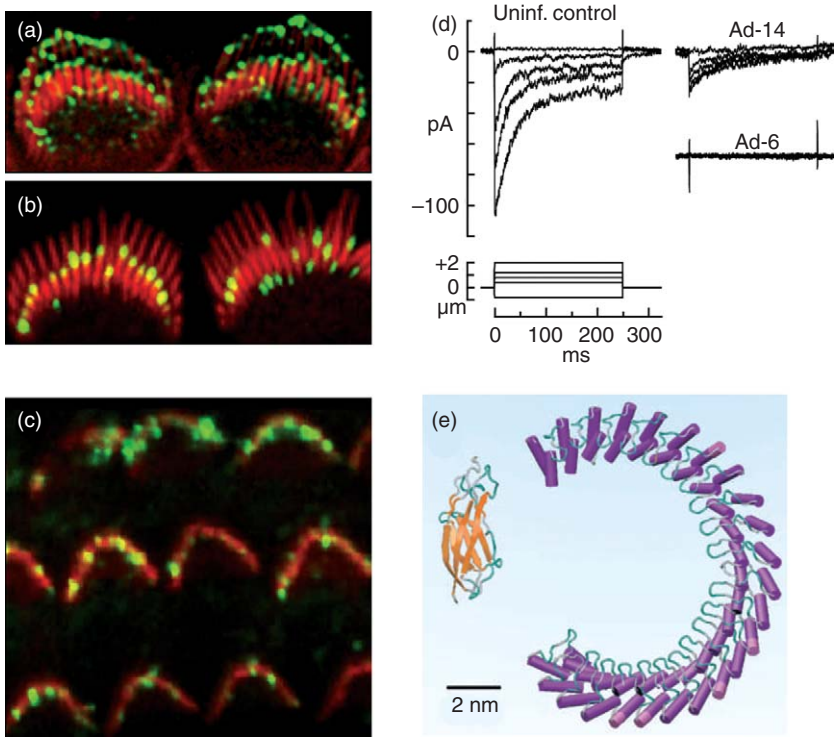

Figure 8 Localization and function of putative transduction molecules. (a) Immunolocalization of cadherin-23 (green) at the tips of stereocilia in inner hair cells from a P5 mouse cochlea. For (a–c), actin is shown in red. (b) Immunolocalization of protocadherin-15 (green) in stereocilia from inner hair cells of a P2 plus 1 day in vitro mouse cochlea. (c) Immunolocalization of TRPA1 (green) at the tips of stereocilia in outer hair cells from a P7 mouse cochlea. (d) Representative transduction currents from uninfected control mouse utricle cells (left) and cells infected with adenoviruses containing siRNAs directed against TRPA1 (right). Ad-6 and Ad-14 contain different siRNA constructs. (e) Models of a single cadherin domain (left) and 24 ankyrin repeats in series (right). Models suggest that a cadherin domain is relatively rigid and inelastic, while ankyrin domains assemble into an elastic spring-like superhelical structure. both the *trans* and *cis* configurations (Goodyear, R and Richardson, G., 2003).

In young mice, cadherin-23 is found throughout the stereocilium, and is most abundant at the tips. In fact, cadherin-23, myosin-7a, and harmonin (a PDZ-containing actin-bundling protein) are all thought to interact during development to shape the cohesiveness of the hair bundle (Frolenkov, G. I. *et al.*, 2004). A defect in any one of these proteins leads to splayed hair bundles, and to Usher's syndrome, which is characterized by vision and hearing deficits. Some hypothesized that cadherin-23 plays a purely developmental role, as it was not initially found in mature stereocilia (Boeda, B. *et al.*, 2002).

However, Siemens J. *et al.* (2004) and Rzadzinska A. K. *et al.* (2005) localized cadherin-23 to the stereociliary tips of mature auditory and vestibular hair cells using a cadherin-23 antibody (Figure 8(a)). The labeling was absent in cadherin-23 deficient mutant mice. The authors went on to localize cadherin-23 intracellularly at tip-link insertion points with immunoelectron microscopy. In bullfrog vestibular cells, cadherin-23 also labeled the kinocilial links between the tallest stereocilia and the kinocilium.

Labeling was abolished in 75% of the hair cells treated with BAPTA, which destroys the tip link.

Cadherin-23 was found to mediate calcium-sensitive, homophilic interactions in a cell aggregation assay. Also, full-length cadherin-23, but not cadherin-23 lacking its cytoplasmic domain, was found to immunoprecipitate with myosin-1c, and to colocalize with myosin-1c when both were expressed in heterologous cells (Siemens, J. *et al.*, 2004). This result is somewhat puzzling, as, based on the mechanotransduction model, myosin-1c was not thought to bind directly to the tip link. The model may be incorrect - myosin-1c may bind to both the tip link and the channel at the lower end of the tip link, for example. In this case, the gating spring could be anchored to the intracellular cytoskeleton, so that the tip link, channel bound to myosin-1c, and gating spring are all in series. However, on the upper end of the tip link, it is difficult to imagine how such an arrangement would allow myosin-1c to exert tension on the channel by climbing. In this case, something other than the tip link would need to exert a force on the channel that opposes the force exerted by a climbing myosin. It remains possible that the assembly may be asymmetric with a different configuration at the upper end of the tip link or that the in vitro binding data do not represent the in vivo arrangement.

Sollner C. *et al.* (2004) separately identified cadherin-23 as a component of the tip link using a genetic approach in zebrafish. A random mutagenesis screen was employed to identify genes involved in vestibular and auditory function. Mutant zebrafish were found to have splayed hair bundles and defects in mechanotransduction. Multiple recessive alleles, all mapped to the cadherin-23 gene, were identified with varying phenotypic severities. Cadherin-23 was localized to the tips of stereocilia, and, importantly, was absent in fish with weak alleles of cadherin-23 that adversely affected mechanotransduction, but not bundle integrity. Transmission electron microscopy identified tip links in wild-type hair bundles, but not in bundles from cadherin-23 mutants.

Taken together, the results of Kachar B. *et al.* (2000), Siemens J. *et al.* (2004), and Sollner C. *et al.* (2004), as well as the similar biochemical and structural properties of cadherin-23 and the tip-link, all suggest that cadherin-23 is a component of the hair cell tip link. Furthermore, cadherin-23 and the tip link both share a number of similar features. Both mediate adhesive interactions between adjacent cell membranes in a calcium-sensitive manner. The tip link is sensitive to degredation by the protease elastase, but not to subtilisin (Goodyear, R. and Richardson, G., 1999a; 1999b). Likewise, cadherin-23 is degraded by elastase, but not by subtilisin (Siemens, J. *et al.*, 2004). Following enzymatic degradation, tip links regenerate within 24 hours. Likewise, cadherin-23 antibody labeling returns 24 hours after enzyme treatment (Siemens, J. *et al.*, 2004). The tip link appears to be a rigid, nonextensible structure consisting of repeating coiled filaments, and cadherin-23 can apparently form homomultimers (Siemens, J. *et al.*, 2004). Corey D. P. and Sotomayor M. (2004) predicted that a tip link could be formed from two parallel dimers of cadherin-23, as a dimer of dimers. Depending on the amount of interdigitation, this structure would be 8–12 nm wide and 140–280 nm long, consistent with the tip link electron microscopy data (Kachar, B. *et al.*, 2000; Corey, D. P. and Sotomayor, M., 2004).

Despite the substantial body of evidence, the conclusion that cadherin-23 is the tip link remains controversial. Other investigators have found that cadherin-23 plays a critical role during hair cell development, but is not present in the mature cell, which would suggest it cannot be a component of the tip link (Boeda, B. *et al.*, 2002; Lagziel, A. *et al.*, 2005; Michel, V. *et al.*, 2005). Michel V. *et al.* (2005) and Lagziel A. *et al.* (2005) both found cadherin-23 localized along the length of stereocilia early during development, was later restricted to the tips of stereocilia, but was no longer detected in the fully mature cell. Using immunogold labeling, cadherin-23 was localized to kinocilial links and to lateral links transiently present within and between stereociliary rows during development of the hair bundle (Michel, V. *et al.*, 2005). The immunolocalization data from these authors and the developmental phenotype of the *waltzer* mouse therefore suggest that cadherin-23 likely plays an essential role in maintaining the structure and cohesiveness of the developing hair bundle, but is not a constituent of the tip link. However, like other putative components of the mechanotransduction apparatus, including the transduction channel itself, the proteins of the tip link may easily elude detection due to exceedingly low expression levels. In addition, modifications to the tip-link proteins, such as glycosylation, may alter their immunoreactivity. The debate over whether cadherin-23 is a component of the tip link or a purely developmental hair cell element will surely continue.

Recently, another protein has emerged that may be a component of the mechano- transduction machinery and, perhaps, the tip link. Protocadherin-15, also a

member of the cadherin superfamily of Ca^{2+}-dependent adhesion glycoproteins, is important for normal hair bundle architecture and inner ear function in humans, mice, and zebrafish (Ahmed, Z. M. *et al.*, 2001; 2003; Alagramam, K. N. *et al.*, 2001a; 2001b; Ben-Yosef, T. *et al.*, 2003; Seiler, C. *et al.*, 2005). Mice carrying mutations in protocadherin-15 suffer from significant inner ear dysfunction and posses hair cells with disorganized bundles. Furthermore, mutant hair cells lack normal mechanotransduction currents (Alagramam, K. N. *et al.*, 2005; Senften, M. *et al.*, 2006). Recently, Ahmed Z. M. *et al.* (2006) identified protocadherin-15 as a component of the tip link antigen which was previously immunolocalized to the tip-link (Goodyear, R. and Richardson, G., 1999a; 1999b). Several splice variants of PCDH15 were identified, each with different localization and expression patterns in the inner ear (Ahmed, Z. M. *et al.*, 2006). While one of the isoforms was localized to the bottom half of stereocilia (Figure 8(b)), another was found just at the stereocilia tips (Ahmed, Z. M. *et al.*, 2006). Ahmed Z. M. *et al.* (2006) suggested that since protocadherin-15 is too short to span the ~150 nm between adjacent stereocilia, it may coassemble with a protein complex that includes cadherin-23, which together confers all the biophysical and structural properties of the filamentous tip link.

3.16.8.6 The Transduction Channel

Mechanosensation is ubiquitous; organisms as diverse as bacteria and blue whales utilize mechanosensation. The first mechanosensitive ion channel to be cloned was the MscL channel in *Escherichia coli*, which is gated by tension within the lipid bilayer and functions in osmoregulation. MscL can be mechanically gated when it is reconstituted in a lipid bilayer (Martinac, B., 2001). In contrast, most vertebrate and invertebrate mechanotransduction channels are thought to be gated by cytoskeletal and extracellular elements. Therefore, the mechanosensitivity of putative vertebrate channels often cannot be reconstituted in heterologous expression systems that lack these elements, making it much more difficult to directly demonstrate that individual proteins function as mechanotransducers.

Two families of ion channel proteins have been found to be necessary for mechanosensation in a variety of cell types: the degenerin/epithelial sodium channel (DEG/ENaC) family of ion channels and the transient receptor potential (TRP) family. In the worm *Caenorhabditis elegans*, a random mutagenesis screen was used to identify genes involved in mechanosensation, the *mec* genes. *MEC-4* and *MEC-10* are members of the DEG/ENac family of ion channels and are expressed in touch-sensitive neurons. They contain two transmembrane-domains, a large extracellular domain and a pore-forming loop. Certain gain-of function mutations in MEC-4 or MEC-10 cause the neurons to degenerate, hence the name degenerin (Huang, M. and Chalfie,M., 1994). MEC-2 and MEC-6 associate with MEC-4 and MEC-10, and can regulate channel activity (O'Hagan, R. *et al.*, 2005). In a heroic series of experiments, O'Hagan, R. *et al.* (2005) applied forces to the body wall of the worm using a flexible glass probe while simultaneously recording from the touch neurons *in vivo*. Null mutations in MEC-4, MEC-2, and MEC-6 did not affect voltage-gated currents in the neurons, but completely abolished mechanotransduction currents. The mechanotransduction currents are carried by Na^+ and can be blocked by amiloride, consistent with the properties of DEG/ENaC channels. Finally, more subtle mutations in specific glycine residues of both MEC-4 and MEC-10 reduced mechanotransduction current amplitudes and shifted the reversal potential of the current. O'Hagan R. *et al.* (2005) concluded that MEC-4 and MEC-10 must carry the mechanotransduction current. By directly demonstrating that the *C. elegans* DEG/ENaC complex composed of MEC-4, MEC-10, MEC-2, and MEC-6 forms a functional sensory mechanotransduction channel, O'Hagan R. *et al.* (2005) were the first to show that specific metazoan proteins are mechanotransducers. Based on similarities with *C. elegans* DEG/ENaC proteins, mammalian mechanosensitive BNaC channels were identified which are expressed in touch receptor cells (Garcia-Anoveros, J. *et al.*, 2001). Targeted gene deletion of BNaC1 caused a loss of touch sensitivity in mice (Price, M. P. *et al.*, 2000) but no deficits in auditory or vestibular function. Although the DEG/ENaC family of ion channels is of considerable interest to inner ear biologists, none of the members of the family have emerged as compelling candidates for the hair cell transduction channel.

Instead, attention has shifted to the TRP family of ion channels as several members were recently cloned from lower organisms, such as fruit flies and zebrafish, where they were found to be important for mechanotransduction (Walker, R. G. *et al.*, 2000; Kim, J. *et al.*, 2003; Sidi, S. *et al.*, 2003). TRP channels were first described in flies, where mutations in the *trp* gene expressed by photoreceptor cells cause transient

voltage responses to a continuous light stimulus (Clapham, D. E., 2003; Moran, M. M. *et al.*, 2004).

The TRP superfamily is extremely diverse, and channels are identified as belonging to the family based on homology, rather than on their selectivity or ligand sensitivity. In mammals, the TRP superfamily contains six subfamilies: the classical TRPs (TRPCs), vanilloid receptor TRPs (TRPVs), melastatin TRPs (TRPMs), the mucolipins (TRPMLs), the polycystins (TRPPs), and TRPA1 (also called ANKTM1, for ankyrin transmembrane protein 1) (Moran, M. M. *et al.*, 2004). The amino acid sequence identity among mammalian TRP channels is as low as 20%. TRP channels are involved in a diverse array of sensory processes, including hot and cold temperature sensation, the signaling of osmotic pressure, taste, alleged pheromone sensation, and mechanosensation (Clapham, D. E. 2003). TRP channels, with the exception of some TRPPs, are all predicted to form subunits consisting of six transmembrane (TM) domains with a pore-loop between TM5 and TM6, and may assemble into oligomers. They are generally nonselective, weakly voltage-sensitive, cation channels. Their properties are quite varied, and single TRP channels are often activated and modulated by multiple types of stimuli, second messengers, or other ligands (Clapham, D. E. 2003).

The fruitfly sensory bristle mechanotransduction channel, *nompC* or no mechanoreceptor potential C (later named TRPN1), was the first mechanosensitive TRP channel cloned (Walker, R. G. *et al.*, 2000). Fly sensory bristles consist of a hair shaft whose base is attached to the dendritic tip of a bipolar sensory neuron. Deflecting the hair shaft compresses the dendritic tip, and gates the mechanotransduction channel. The fly bristle mechanotransduction process is remarkably similar to the mammalian hair cell transduction process, in that it exhibits directional sensitivity, a submillisecond response latency, sensitivity to nanometer-scale deflections, a steep I(X) relationship, and similar adaptation. Flies carrying loss-of-function mutations in the *nompC* gene exhibit transduction currents that are ~10% of the wild-type response. Another *nompC* allele exhibits nearly normal transduction, but abnormally fast adaptation. The *nompC* gene was cloned, and found to encode a previously unidentified ion channel with 29 ankyrin (ANK) repeats on its NH_2-terminus, and six predicted transmembrane domains with a pore region between TM5 and TM6 (Walker, R. G. *et al.*, 2000).

The first putative vertebrate mechanotransduction channel to be cloned was the zebrafish ortholog of *nompC*. Zebrafish *nompC*, like fly *nompC*, belongs to the TRPN family within the TRP superfamily. It also contains 29 ANK repeats in its NH_2-terminus. Zebrafish injected with anti-sense morpholinos to disrupt *nompC* expression lacked an acoustic startle response. Hair cells within the ear of injected zebrafish did not take up the styryl dye FM-1-43, which permeates the transduction channel. Microphonic potentials, which are generated by current flowing through the transduction channels in a population of hair cells, were abolished in morpholino-injected zebrafish. The amount of dye uptake and the reduction in microphonic potential amplitudes were correlated with the severity of the acoustic startle phenotype. Finally, all three phenotypes were reversible; 24 hours after the morpholinos washed out nompC expression and all of the phenotypes returned to normal. Sidi S. *et al.* (2003) searched the mouse and human genomes but *nompC* homologs were not found.

The remarkable similarities between fruitfly mechanosensory bristle transduction, zebrafish hair cell transduction, and vertebrate hair cell mechanotransduction suggest that they may all use similar mechanotransduction channels. Yet, since *nompC* is not found in mammals, what is the mammalian transduction channel? The properties of the channel, namely its large single-channel conductance and permeability to cations, as well as the blocking effect of extracellular calcium, all suggest that it could be a member of the TRP family of ion channels.

In 2004 TRPA1 was presented as a mammalian hair cell transduction channel candidate (Corey, D. P. *et al.*, 2004, Nagata, K. *et al.*, 2005), but the suggestion remains controversial. TRPA1 was previously identified as a nonselective cation channel activated by noxious cold (~<17 °C) in a subset of nociceptive dorsal root ganglia neurons (Story, G. M. *et al.*, 2003; Bandell, M. *et al.*, 2004). TRPA1 is also activated by isothiocyanate compounds, such as mustard oil and wasabi, Delta(9)-tetrahydrocannabinol (THC) (Jordt, S. E. *et al.*, 2004), allicin, an unstable component of fresh garlic (Macpherson, L. J. *et al.*, 2005), and other pungent compounds such as in cinnamon oil (cinnamaldehyde), wintergreen oil (methyl salicylate), clove oil (eugenol), and ginger (gingerol) (Bandell, M. *et al.*, 2004).

Corey D. P. *et al.* (2004) presented TRPA1 as a candidate for the mammalian hair cell transduction channel based on several lines of indirect evidence. Corey D. P. *et al.* designed *in situ* hybridization probes for 33 TRP channels within the mouse genome, and looked for expression in the mouse ear. Only TRPA1

labeled hair cells above background levels. Hair cells of the mouse utricle first become sensitive to mechanical stimuli around embryonic day 17 (Géléoc, G. S. and Holt, J. R., 2003a). Quantitative RT-PCR was used to assess mRNA levels of various TRP channels during development of the mouse utricle, and TRPA1 levels were found to steadily increase to a prominent peak at E17. An antibody to the carboxy terminus of TRPA1 labeled the upper half of bullfrog stereocilia, along the length of the kinocilium, and the pericuticular zone around the cuticular plate. Light labeling was seen in the cell body. In mouse vestibular hair cells, light stereociliary labeling could be seen, along with stronger labeling within the kinocilium and pericuticular zone. In mouse auditory hair cells, labeling was the strongest in the stereocilia, but could be seen in the cell bodies (Figure 8(c)). Labeling at stereociliary tips could be seen in auditory hair cells from animals older than postnatal day 4. Interestingly, TRPA1 labeling in the stereocilia, like that of cadherin-23, was greatly diminished after treating cells with BAPTA or La^{3+} to break the tip links (Corey, D. P. *et al.*, 2004).

Corey D. P. *et al.* (2004) first inhibited TRPA1 expression in zebrafish hair cells. In zebrafish embryos injected with antisense morpholinos designed to inhibit TRPA1 protein expression, FM1-43 dye uptake by hair cells was significantly reduced, as compared to controls. Microphonic potentials, which result from current flow through transduction channels from multiple hair cells, were also reduced. TRPA1 morpholinos did not appear to simply delay hair cell development, as control and TRPA1 morpholino-injected fish had a similar number of hair cells. Finally, RT-PCR of TRPA1 message and immunoblots of extracted protein confirmed that TRPA1 levels were reduced in TRPA1 morpholino-injected animals as compared to control-injected animals. If TRPA1 and TPRN1 (*nompC*) are both required for hair cell transduction in zebrafish, it may be because they form heteromultimers together, or possibly because individual hair cells use one or the other (Corey, D. P. *et al.*, 2004).

Next, the functional consequences of inhibiting TRPA1 expression in mouse hair cells were investigated. Two hairpin small interfering RNAs (siRNAs) that targeted TRPA1 were packaged into adenoviral vectors along with the gene for green fluorescent protein. Mouse utricular hair cells were infected with the TRPA1 adenoviruses at embryonic day 16, before the onset of mechanotransduction. The authors recorded transduction currents at embryonic day 17–20 from siRNA treated cells, cells exposed to a control vector that expressed GFP alone and uninfected control cells. Both siRNA constructs yielded cells with reduced FM1-43 uptake and transduction current amplitudes relative to uninfected control cells (Figure 8(d)). From these data, the authors concluded that expression of siRNAs directed against TRPA1 resulted in a loss of hair cell mechanotransduction (Corey, D. P. *et al.*, 2004).

Based on the immunolocalization data, expression analysis, knock-down, and functional data, TRPA1 seemed a reasonable candidate for the hair cell transduction channel. However, recent data call that suggestion into question. Two groups generated mice that carried a targeted gene deletion of TRPA1, and both found that hearing and balance function in the knockout animals was identical to wild-type controls (Bautista, D. M. *et al.*, 2006; Kwan, K. Y. *et al.*, 2006). Furthermore, Kwan K. Y. *et al.* (2006) found normal FM1-43 uptake and mechanotranduction currents in $TRPA1^{-/-}$ animals. Several possibilities exist that may reconcile the observations of Corey D. P. *et al.* (2004) and Nagata K. *et al.* (2005) with those of Kwan K. Y. *et al.* (2006) and Bautista D. M. *et al.* (2006). First, TRPA1 could be an integral member of the transduction apparatus, coupling (either directly or indirectly) the actual transduction channel to the cytoskeleton using its ankyrin repeats (see Section 3.16.8.7). TRPA1 localizes along the kinocilium, and, like cadherin-23, at kinocilial links between the tallest stereocilia and the kinocilium. With its long ankyrin domain, TRPA1 could simply play a structural role in this location, as the kinocilium itself is not mechanosensitive. It is possible that TRPA1 is a nonessential structural component of the mechanotransduction apparatus. Secondly, it could be argued that TRPA1 plays a purely developmental role. Disruption of TRPA1 expression with siRNA- adenoviruses was performed between embryonic day 15 and 18 (Corey, D. P. *et al.*, 2004) whereas TRPA1-deficient mice were examined at later postnatal and adult stages (Kwan, K. Y. *et al.*, 2006). Third, the siRNAs designed to inhibit TRPA1 expression may have had unintended, nonspecific effects on the expression of other molecules required for transduction. Lastly, it remains a possibility that expression of some other transduction channel subunit compensated for the lack of TRPA1 expression in the knockout mice. Whatever the reason, two important questions remain. If TRPA1 is not the transduction channel, what is? And furthermore, what is the function of TRPA1 in hair cells?

Another TRP channel expressed in hair cells is TRPML3 (Di Palma, F. *et al.*, 2002). Mutations in TRPML3 are responsible for hair bundle disorganization, circling behavior, and hearing loss in the varitint-waddler mouse. TRPML3 localizes primarily to organelles within the cell body, suggesting that deafness results from abnormal organelle trafficking, rather than from defects in transduction. However, TRPML3 has not been ruled out as candidate for the hair cell transduction channel. A third candidate is TRPV4 (previously named VR-OAC), a mechanically sensitive channel that is activated by osmotic changes (cell swelling), fluid flow, and by heat. TRPV4 is expressed by multiple cells types within the inner ear, including the hair cells and the marginal cells within the stria vascularis. TRPV4 knockout mice have hearing deficits, but the deficits only appear in older mice and only shift hearing thresholds by about 20 dB. The mechanical activation of TRPV4 is also relatively slow, suggesting that a second messenger is involved, which is inconsistent with the rapid kinetics of the hair cell transduction channel (Corey, D. P., 2006). Although multiple candidates have been identified, the molecular identity (or identities) of the hair cell mechanotransduction channel is still unknown.

3.16.8.7 The Gating Spring

The tip link ultrastructural data and the finding that cadherin-23 (Figure 8(a)) and protocadherin-15 (Figure 8(b)) may be components of the tip link suggest that the tip link does not have the requisite elastic properties of the biophysically defined gating spring. Cadherin domains are predicted to be stiff and relatively inextensible. Furthermore, large forces would probably cause the complete unfolding of the cadherin repeat structure (Sotomayor, M. *et al.*, 2005), a characteristic poorly suited for the gating spring. Therefore, the search for the molecular correlate of the gating spring has recently shifted elsewhere. The gating spring may consist of the collective elasticity of multiple molecular elements in series with the transduction apparatus or it may be a single, as of yet, unidentified molecule. Several candidates have been proposed, including the 17 ankyrin repeats of TRPA1. TRPA1 is the only known mammalian TRP channel that, like *nompC*, contains a large number of ankyrin repeats in its NH_2-terminus. Ankyrin repeats have the ability to mediate protein-protein interactions by forming a scaffold that exposes certain interacting, or binding interfaces (Main, E. R. *et al.*, 2003). Ankyrin motifs consist of repeating units of 33 amino acids. Two anti-parallel alpha helices within the motif are linked by a beta hairpin/loop that is almost perpendicular to the alpha helices, thereby producing an L shape conformation. In the majority of ankyrin-mediated protein-protein interactions, the beta hairpin/loop region acts as the binding surface. Multiple ankyrin repeats stack together in parallel, and the stacking interactions cause a slight curvature and left-handed twist in the overall structure (Figure 8(e)) (Main, E. R. *et al.*, 2003).

Howard J. and Bechstedt S. (2004) suggested that a helix of ankyrin repeats within *nompC* may be the gating spring of zebrafish hair cells; might participate in gating the transduction channel of fruitfly mechanosensory bristles; and possibly act as the biophysically defined gating spring of mammalian hair cells as well. 29 ANK repeats are predicted to form almost exactly one helical turn with an expected stiffness of 1 mN m^{-1}. If *nompC* assembles into a tetramer, then four helices would have an upper limit stiffness of 4 mN m^{-1}. These values are similar to the stiffness of the gating spring of vertebrate hair cells (1 mN m^{-1}) and the fly hair bristle receptor (3 mN m^{-1}). Furthermore, molecular dynamic simulations suggested that the 17 ankyrin repeats found in TRPA1 would have a stiffness of a few mN m^{-1}, and that large forces can pull apart the packed alpha helices to extend the protein nearly tenfold, possibly acting as a safety release for extreme stimuli (Sotomayor, M. *et al.*, 2005). In addition, an ankyrin spring is predicted to have a relaxation time constant in the nanosecond range. As such, Corey D. P. *et al.* (2004) suggested that the ankyrin repeats of TRPA1 may act as the biophysically defined gating spring. But here again the lack of a hair cell transduction phenotype and hearing or vestibular deficits in the TRPA1-deficient mice call this attractive suggestion into question.

3.16.9 Conclusions

The biophysical properties of hair cell mechanotransduction and adaptation are fairly well understood. A flurry of recent activity has led to a number of suggestions regarding the molecular identity of components of the hair cell mechanotransduction complex (Figure 9). Cadherin-23 and protocadherin-15, myosin-1c and/or myosin-7a, TRPA1 and TRPML3, TRPV4 may play integral roles in hair cell mechanotransduction and adaptation, but many uncertainties remain. The identity of other molecular components, including the adaptation extent spring, the negative

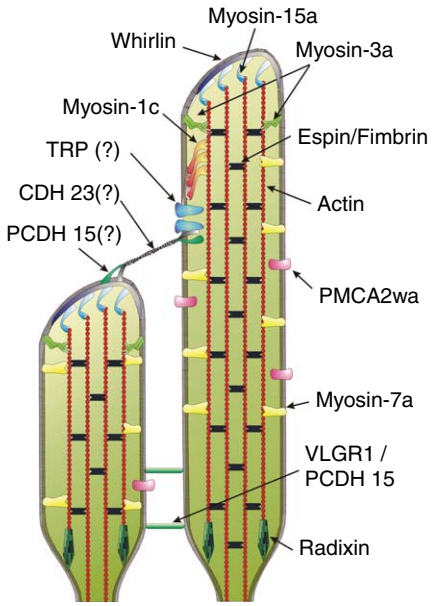

Figure 9 A schematic diagram showing known and hypothesized molecular components of the mechanosensory hair bundle.

limit and the fast adaptation mechanism, are still unknown. Other outstanding questions include: how are these components configured to render the fully functional mechanotransduction apparatus? By what molecular mechanism does conductance vary along the length of the cochlea? What role do second messengers or membrane phospholipids play in the transduction and adaptation processes? Does the transduction channel consist of heteromultimers of TRP or Deg/ENaC subunits? Do myosin-1c and myosin-7a, contribute to hair cell adaptation together or separately? Does the channel interact directly with myosin-1c or myosin-7a? Does the transduction apparatus contribute to active hair bundle movements that drive cochlear amplification?

Hair cell mechanotransduction and adaptation, like many biological processes, is probably more complex than first imagined. Even if the molecular components proposed thus far turn out not to be involved, the proposals themselves have accelerated the pace of research to either confirm or refute the hypotheses. Thus, the search continues for the channel and the rest of the components of this exquisite mechanosensitive system. As a final caveat, the transduction and adaptation model presented here will undoubtedly need to be modified as new discoveries clarify the true molecular and biophysical nature of hair cell transduction and adaptation. Stay tuned!

3.17.1 Introduction

Sensitive hearing, as known from vertebrates, also occurs in certain invertebrates: many insects are endowed with exquisitely sensitive ears (see Chapter Insect Ears). The auditory systems of vertebrates and insects have evolved independently, display different anatomies, and house different types of mechanosensory cells: insect hearing relies on stretch-sensitive chordotonal sensory neurons that bear a true sensory cilium but lack the actin-based stereociliar hair bundle characteristic of vertebrate hair cells (see Chapter Biophysics of Chordotonal Organs). Notwithstanding this anatomical difference, it now appears that insect chordotonal neurons and vertebrate hair cells improve the sensitivity of hearing in equivalent ways: like hair cells, chordotonal neurons seem to generate forces to actively boost the mechanical sensitivity and frequency selectivity of the ear. This mechanical feedback amplification, its manifestations in the auditory mechanics, its cellular and molecular basis, and its evolution are the topic of this chapter, which reviews our current knowledge about the mechanical feedback processes in invertebrate ears.

3.17.2 Evidence for Mechanical Feedback Amplification in Insect Auditory Systems

3.17.2.1 Essential Characteristics of Mechanical Feedback Amplification

Feedback implies that the output signal, or some function thereof, is passed back to the input and modifies it. In hearing, the input signal is the mechanical vibration sound induces in the ear. This vibration, in turn, can trigger a mechanical output signal, which, in vertebrate auditory system, is an active, motile response of mechanosensory cells. Provided this motile response is constructively coupled back into the sound-induced vibration, it will amplify this vibration and, accordingly, augment the mechanical input of the ear. Mechanical feedback amplification introduces novel characteristics in the mechanics of the systems. In vertebrate auditory systems, these characteristics include (1) a compressive nonlinearity that condenses a wide range of sound intensities into a narrow range of responses by specifically boosting the mechanical sensitivity to low intensity sounds; (2) frequency-dependent amplification, whereby vibrations at certain frequencies are selectively enhanced; (3) power gain, reflecting the increase in the mechanical energy due to active energy contributions; and (4) self-sustained oscillations and their acoustic equivalent, spontaneous otoacoustic emissions, which may result from excessive feedback exerted by mechanosensory cells inside the ear (Dallos, P. *et al.*, 1996; Hudspeth, A. J., 1997; Manley, G. A., 2001; Robles, L. and Ruggero, M. A., 2001; Chan, D. K. and Hudspeth, A. J., 2005, see also Chapter Otoacoustic Emissions). Because all these characteristics are essentially linked to feedback amplification (Kruse, K. and Jülicher, F., 2005), they can be used to probe the existence of comparable feedback processes in other mechanosensory systems such as insect ears.

3.17.2.2 Signatures of Mechanical Feedback Amplification in Insect Ears

All the four essential characteristics of the amplificatory feedback that have been identified in vertebrate auditory systems have also been documented for insect ears. In the antennal hearing organ of the fruit fly *Drosophila melanogaster*, for example, nonlinear compression is observed when the vibrations of the sound receiver formed by the distal part of the antenna (Figure 1(a)) are measured in response to pure tones of different intensity. As long as the tone intensity is either very high or very low, the mechanical sensitivity of the receiver scales linearly with the loudness of the tone (Figure 1(b)). For intermediate intensities, however, a nonlinear relation is found: the sensitivity of the receiver increases as the stimulus intensity declines, leading to a *c.* tenfold gain in sensitivity for low-intensity sounds (Figure 1(b)). This compressive nonlinearity, which is reminiscent of that reported for actively oscillating hair bundles of frog hair cells (Martin, P. and Hudspeth, A. J., 2001), is only observed if the frequency of the tone approximates the best frequency of the receiver (*c.* 200 Hz, Figure 1(b)). If the stimulus frequency is much higher (600 Hz or more), the mechanical sensitivity of the receiver remains constantly low throughout the entire intensity range (Göpfert, M. C. *et al.*, 2006). Hence, nonlinear amplification in insects is frequency-specific, analogous to the frequency-dependent amplification in vertebrate hearing (Martin, P. and Hudspeth, A. J., 2001; Robles, L. and Ruggero, M. A., 2001).

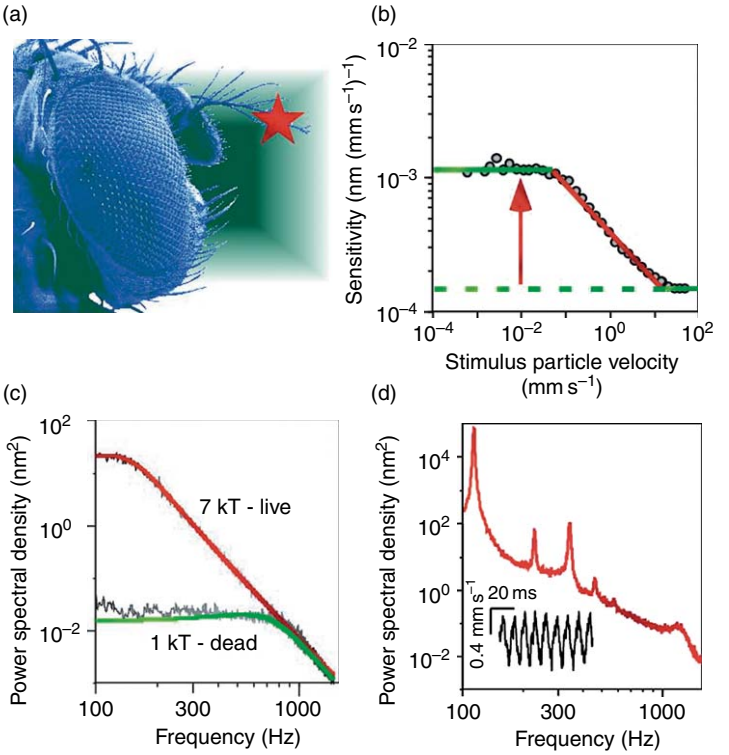

Figure 1 Signatures of feedback amplification in the mechanics of the *Drosophila* ear. (a) Lateral view of the *Drosophila* head depicting the measurement site (red star) on the antennal receiver from which the measurements in (b)–(d) were obtained. (b) Nonlinear amplification revealed by stimulating the receiver near its best frequency with pure tones of different intensities. Intensity is measured as particle velocity, and the mechanical sensitivity is expressed as the ratio between the phase-locked displacement of the receiver and the stimulus particle velocity. Green lines depict linear regimes, red lines nonlinear regimes, and the arrow indicates the gain in sensitivity due to nonlinear amplification. (c) Power gain. Power spectra of the mechanical fluctuations of a receiver (black traces) measured *in vivo* and postmortem and corresponding harmonic oscillator models (red and green lines). *In vivo*, the mean total energy of the fluctuations is lifted from 1 kT (thermal energy) to 7 kT, demonstrating that energy is injected into the system (for a detailed description, see Göpfert, M. C. *et al.*, 2005). (d) Self-sustained oscillations. Power spectrum and time trace (inset) of the displacement of a receiver oscillating spontaneously in the absence of external stimulation.

Nonlinear, frequency-specific amplification, as described here for the fly's auditory system, has also been documented for the antennal hearing organs of mosquitoes (Göpfert, M. C. and Robert, D., 2001) and seems also present in the tympanal ears of locusts (Kössl, M. and Boyan, G. S., 1998a; 1998b) and moths (Coro, F. and Kössl, M., 1998; 2001). In *Drosophila*, this amplification was shown to associate with power gain: mechanical measurements on live, dead, and mutant flies revealed that the receiver fluctuations in intact live flies exceed thermal noise (Göpfert, M. C. *et al.*, 2005); the mechanical energy of the fluctuations was found to amount to *c.* six times the thermal energy (Figure 1(c)), demonstrating that the fly expends biological energy to actively improve the mechanical sensitivity of its ear. Also the fourth characteristic of mechanical feedback amplification, self-sustained oscillations, has been documented for invertebrate ears: the antennal sound receivers of mosquitoes and *Drosophila* occasionally oscillate spontaneously with large amplitudes in the absence of acoustic stimulation (Göpfert, M. C. and Robert, D., 2001; 2003) (Figure 1(d)). These self-sustained oscillations, which cannot be explained by the activity of muscles, reliably occur when the physiological condition of the animal deteriorates, for example, after heat application to the thorax or after thoracic injection of ethanol of dimethylsulfoxide (DMSO). As described in the next section, self-sustained oscillations in the *Drosophila* auditory system can also result from genetic defects.

3.17.3 Cellular and Molecular Basis of Mechanical Feedback Amplification in Invertebrates

3.17.3.1 Genetic Dissection of Mechanical Feedback Amplification

The signatures of feedback amplification observed in the mechanics of insect auditory system suggest that insect chordotonal neurons, like vertebrate hair cells, are motile and exert feedback on the mechanics of the ear. Active movements of insect chordotonal neurons have hitherto not been directly observed, yet the motility of these cells has been inferred from the effects of genetic mutations on the mechanics of the ear (Göpfert, M. C. and Robert, D., 2003; Göpfert, M. C. *et al.*, 2005). In *Drosophila*, the signatures of feedback amplification observed in the mechanics of the antennal receiver are reportedly abolished by mutations in *no mechanoreceptor potential A* (*nompA*), *touch insensitive larva B* (*tilB*), and *beethoven* (*btv*) (Figure 2). All these mutations affect the chordotonal neurons in the antenna's base. *nompA*, for example, encodes a tectorin-related extracellular linker protein that connects the neurons to the antennal receiver (Chung, Y. D. *et al.*, 2001). Mutations in *nompA* disrupt this connection, separating the neurons from the receiver. Because this anatomical transection makes the receiver's mechanics linear and passive, it appears that the receiver is usually driven by the chordotonal neurons that connect to its base. Force generation by chordotonal neurons is supported by the elimination of the receiver's nonlinearity, self-sustained oscillations, and power gain by mutations in *tilB* and *btv*: these mutations specifically affect the structural and functional integrity of cilia, including the sensory cilia of the chordotonal neurons in the ear (Eberl, D. F. *et al.*, 2000). Also the transient receptor potential (TRP) channel (see Chapter Hair Cell Transduction and Adaptation: Physiology and Molecular Mechanisms) *NompC* (also known as *TRPN1*) is required for mechanical feedback amplification in the *Drosophila* ear: genetic disruption of this channel virtually abolishes

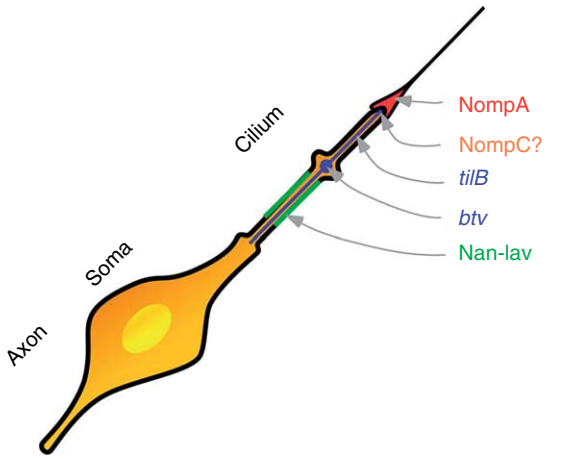

Figure 2 Molecular components involved in the mechanical feedback in the *Drosophila* ear. In the fly, feedback amplification is reportedly affected by mutations in *nompA*, *nompC*, *tilB*, *btv*, *nan*, and *iav*. *NompA* localizes to the extracellular cap that connects the auditory sensory neurons to the antennal receiver (Chung, Y. D. *et al.*, 2001). The NompC (=TRPN1) channel, though not definitely localized yet, may be a component of the ciliary tip. Mutations in *tilB* affect the structure of the ciliary axoneme, whereas mutations in *btv* cause structural defects of the ciliary dilation, a swelling in the distal region of the cilium (Eberl, D. F. *et al.*, 2000). In the region of the cilium proximal to the ciliary dilation, the Nan-Iav TRP channels are found (Kim, J. *et al.*, 2003; Gong, Z. *et al.*, 2004).

nonlinear amplification, and only some subtle nonlinearity seems to remain (Göpfert, M. C. and Robert, D., 2003; Göpfert, M. C. *et al.*, 2006). Interestingly, the opposite effect results from the disruption of another, presumably heteromultimeric TRP channel formed by the interdependent TRPV channel proteins Nanchung (Nan) and Inactive (Iav) (Kim, J. *et al.*, 2003; Gong, Z. *et al.*, 2004): mutations in the genes encoding for this channel facilitate amplification and induce self-sustained oscillations in the ear (Göpfert, M. C. *et al.*, 2006). Hence, while NompC is required for amplification, Nan-Iav seems required for adjusting the amplificatory gain. As shown by the examination of double mutants, this gain control requires NompC function, suggesting that NompC channel acts upstream of Nan-Iav. This functional placement accords with the presumptive anatomical placement of the two channels, for Nan-Iav localizes to the proximal region of the sensory cilia (Kim, J. *et al.*, 2003; Gong, Z. *et al.*, 2004), whereas – at least in frog hair cells – NompC localizes to ciliary tips (Shin, J. B. *et al.*, 2005) (Figure 2).

3.17.3.2 Candidate Sensors and Motors of the Feedback Loop

While the examination of *Drosophila* mutants has provided insights into the cellular basis of active amplification in invertebrate auditory systems (Figure 3), the identities of the sensor and motor elements that promote the feedback have remained unclear. Because all of the mutations mentioned above seem to affect both transduction and amplification, it seems plausible to assume that the sensor elements that sample the input signal in the course of the feedback are those ion channels that mediate

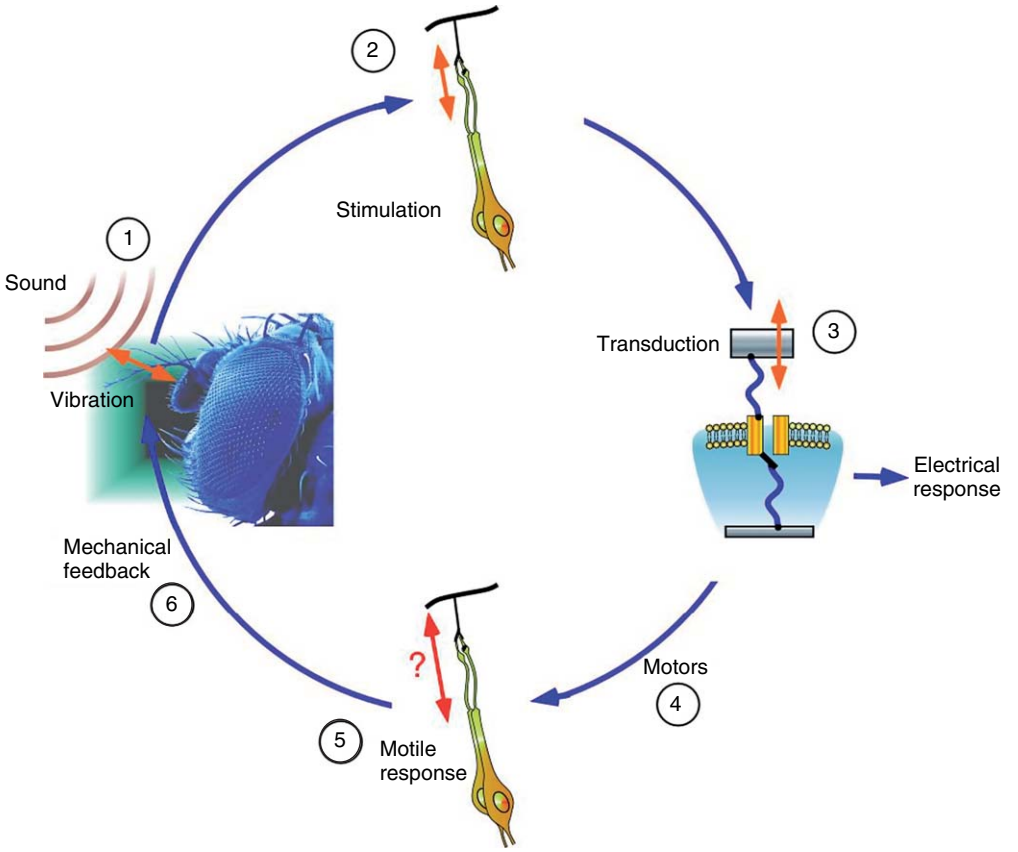

Figure 3 Simple scheme of the amplificatory feedback in *Drosophila* hearing. Sound-induced vibrations of the fly's antennal sound receiver (1) are directly coupled to the auditory neurons (2) and the mechanotransducer channels these neurons comprise (3). The resulting opening of channels leads to an electrical response and, in addition, triggers the activity of motors (4), leading to active mechanical responses of the cells. (5) This mechanical activity is coupled back into the receiver's vibrations (6), resulting in a mechanical feedback that amplifies the receiver's mechanical response to sound.

transduction in the *Drosophila* ear (Figure 3). Channels that have been proposed as candidate transducer in the fly's auditory system are the TRPs Nan-Iav and NompC (Eberl, D. F. *et al.*, 2000; Walker, R. G. *et al.*, 2000; Kim, J. *et al.*, 2003; Gong, Z. *et al.*, 2004). Of these two channels, NompC seems the better candidate, given its requirement for feedback amplification and its apparent functional and anatomical placement upstream of Nan-Iav. Disrupting the NompC channel, however, does not fully eliminate sound-induced electrical responses of the fly's auditory neurons (Eberl, D. F. *et al.*, 2000). Hence, NompC may participate in auditory transduction, but seems unlikely to be the only transducer in the *Drosophila* ear.

Also for the motor elements that exert the feedback in insect auditory systems (Figure 3), several candidates exist. Because chordotonal neurons are ciliated cells, it may well be that amplification involves active, kinesin- or dynein-driven movements of sensory cilia, in analogy to the cilium-based motility of sperm. This possibility is supported by the effects of mutations in *Drosophila tilB*, which abolish ciliary dynein arms, eliminate the amplificatory feedback, and lead to the immobility of sperm (Eberl, D. F. *et al.*, 2000; Göpfert, M. C. and Robert, D., 2003; Todi, S. V. *et al.*, 2004). Whether *tilB* codes for a dynein motor or an associated protein has not yet been determined. A second possibility is that force-generation by chordotonal neurons involves homologues of the mammalian outer hair cell motor protein prestin (see Chapter Prestin); prestin-related proteins are reportedly expressed in the antennal hearing organs of *Drosophila* and mosquitoes (Weber, T. *et al.*, 2003), yet whether these insect proteins serve as motors remains to be seen: a null allele of the *Drosophila* prestin gene has been generated, and its effects on the mechanical feedback amplification are currently being examined (Fritz, J. *et al.*, personal communication). Analogous to the hair bundle motility of hair cells, feedback amplification in invertebrate auditory systems may also rely on the interplay between the auditory transducer channels and associated adaptation motors (see Chapter Hair Cell Transduction and Adaptation: Physiology and Molecular Mechanisms). Adaptation characteristics as known from vertebrate hair cells have been documented for NompC-dependent currents in *Drosophila* sensory bristles, suggesting that insect mechanotransducer channels can associate with adaptation motors as well. Moreover, the fly's genome sequence comprises two close relatives of the hair cell adaptation motor myosin1c, which may contribute to active amplification. Whether dyneins, prestin homologs, or myosin1c relatives are the motors that promote active amplification in insect hearing cannot be answered yet. Given the list of candidates, however, it seems well possible that the motor mechanisms insects employ for amplification turn out to be similar to those found in vertebrate ears.

3.17.4 Parallel Evolution of Mechanical Feedback Amplification in Vertebrates and Invertebrates

The finding that mechanical feedback amplification, one of the presumably most elaborate aspects of vertebrate hearing, also occurs in certain invertebrates seems surprising as insects and vertebrates are only distantly related and independently evolved their ears (see Chapters Phylogeny and Evolution of Ciliated Mechano-Receptor Cells and Insect Ears). Accordingly, it seems most likely that the use of mechanical feedback has been independently invented within vertebrates and insects to improve the sensitivity of their ears. Such parallel evolution does not exclude the possibility that some of the molecular modules both groups employ for generating the feedback are evolutionarily conserved. Although the ears of insects and vertebrates have formed independently, evidence is accumulating that the mechanosensory cells that mediate hearing in these taxa have been derived from a common ancestral cell: insect chordotonal neurons and vertebrate hair cells are developmentally specified by homologous genes (Hassan, B. A. and Bellen, H. J., 2000) and share a variety of conserved molecular modules for mechanosensory cell formation and function (Fritzsch, B. and Beisel, K. W., 2004; Boekhoff-Falk, G., 2005, see Chapter Phylogeny and Evolution of Ciliated Mechano-Receptor Cells). Chordotonal neurons, for example, seem to express close relatives of motors implicated in amplification by hair cells and, conversely, hair cells express close relatives of channels chordotonal neurons need for amplification (see Chapter Hair Cell Transduction and Adaptation: Physiology and Molecular Mechanisms). Future research will show whether insects and vertebrates went back to the same conserved modules when independently implementing mechanical feedback into their ears.

3.17.5 Mechanical Feedback Amplification in Other Invertebrate Mechanosensory Systems?

One aspect that has hitherto not been addressed is whether the use of mechanical feedback amplification within invertebrates is unique to insect hearing, or whether other types of invertebrate mechanosensors employ the same trick. Invertebrates display an almost bewildering diversity of mechanosensory organs, including simple single-celled stretch receptors that, like chordotonal neurons and nonmammalian hair cells, express the NompC channel (Li, W. *et al*., 2006), and hair cell-based sensors such as the prey detectors of sea anemones and the balance organs of jellyfish, snails, mussels, and squids (Budelmann, B. U., 1988; Thurm, U. *et al*., 1997; Watson, G. M. *et al*., 1997). Testing for signatures of mechanical feedback amplification in these invertebrate systems may well hold some surprises, much as it still does in insect and vertebrate ears.

Acknowledgments

I would like to thank Jörg Albert and Björn Nadrowski for valuable comments and suggestions and the Volkswagen-Foundation for its support.

Glossary

air conduction of sound Transmission of sound to the inner ear through the external auditory canal and middle ear.

anechoic chamber A room designed to absorb all sound to eliminate echo, used in auditory research.

audiometrically Performed with the use of an audiometer.

bone conduction of sound Transmission of sound to the inner ear through the bones of the skull.

characteristic frequency The frequency at which a neuron responds to the least intensity of sound.

cholinergic system The source of cholinergic agents (nucleus basilis) and the neurons that respond to them.

cochlear nucleus Brainstem center of the auditory pathway receiving input from the auditory nerve and providing the major output to the lateral lemniscus.

conditioned suppression Cessation or reduction of a learned response when the conditioned or warning stimulus is presented.

conductive hearing impairment or loss Hearing impairment or loss due to a lesion in the external auditory canal or middle ear.

decibel A unit of sound on a logarithmic scale used to measure hearing and sound; one-tenth of a bel, named after Scottish-American scientist, Alexander Graham Bell, 1847–1922.

dorsal cochlear nucleus The dorsal portion of the cochlear nucleus.

edge effect A contrast between two adjacent qualities.

effusion in the middle ear Fluid in the middle ear associated with otitis media.

external nucleus of the inferior colliculus Neuronal center located peripherally in the inferior colliculus.

frequency of sound Number of regular recurrences of vibrations of sound, measured in cycles per second; primary determinate of the pitch of a sound.

functional magnetic resonance imaging Use of magnetic resonance to measure the metabolic activity of a tissue or organ.

ginkgo biloba Extract of the leaves of the ginkgo tree, containing ginkgoheterosides and terpene lactones used medicinally in vascular insufficiency.

hertz A unit of frequency, one cycle per second, named after German physicist, Heinrich R. Hertz, 1857–1894.

hyperactivity Increased neuronal activity.

hyperacusis Physical discomfort from exposure to low or moderate sound intensity.
incidence Number of persons acquiring a new specific disease or disorder during a specific period of time in a specific population.
inferior colliculus Midbrain center of the auditory pathway receiving input from the lateral lemniscus and providing output to the medial geniculate body.
intense sound sound exceeding 85 dB sound pressure level, capable of causing a temporary threshold shift in hearing or permanent hearing impairment.
intensity of sound An objective measure of the amplitude of sound waves, expressed in decibels; primary determinant of the loudness of sound.
lemniscal pathway in the auditory system The pathway in the auditory system in the brain that is tonotopically organized and does not receive non-auditory input; it is characterized by the lateral lemniscus.
loudness The psychophysical attribute that depends on the intensity of sound.
maskability of tinnitus The intensity at which a specific spectrum of sound makes tinnitus imperceptible.
Meniere's disease A disease of the inner ear causing fluctuating and progressive hearing loss, episodic vertigo, low-pitched tinnitus and a feeling of aural fullness; its pathologic correlate is endolymphatic hydrops.
misophonia Strong dislike or hate of sound.
neuromodulatory systems Brain systems that produce and respond to specific neurotransmitters, as, for example, the cholinergic, serotonin, dopaminergic, and noradrenergic systems.
nonlemniscal pathway in the auditory system The pathway of the auditory system in the brain which is not tonotopically organized and receives multimodal (somatosensory and auditory) input.
objective tinnitus Tinnitus produced by body sound that can be heard or monitored by others.
octave The frequency interval between two tones that have a hertz ratio of 2:1.
otitis media Inflammation of the middle ear.
otoacoustic emissions Sound coming for the inner ear that can be measured in the external auditory canal, arising from the motion of the outer hair cells.
otosclerosis A disease affecting the bone encasing the inner ear and resulting in fixation of the footplate of the stapes and causing conductive and sensorineural hearing losses.
passive avoidance A procedure in which the adversive stimulus is delivered only if the subject fails to suppress a learned behavior when a conditioned stimulus is presented.
percept That which is perceived: a sensation or experience.
pitch The psychophysical attribute that depends on the frequency of the sound.
placebo effect The suggestive effect that occurs in response to an inert form of treatment.
positron emission tomography Images of metabolic activity in tissue with computer analysis of positrons emitted when radioactive substances are incorporated into the tissue.
prevalence Number of persons with a specific disease or disorder in a specific population at a specific time.
primary auditory cortex A major part of the auditory cortex; the other major parts are the secondary auditory cortex and the anterior auditory field.
psychoacoustic parameters of tinnitus They include pitch, loudness, timbre, and localization.
pulsatile tinnitus Objective tinnitus that is synchronous with the heartbeat.
selective serotonin reuptake inhibitors A group of relatively new antidepressive agents which act by inhibiting the re-uptake of serotonin in the vicinity of synapses.
sensorineural hearing impairment or loss Hearing impairment or loss due to a lesion in the inner ear or auditory nerve.
serotonin system The source of serotonin (raphe nuclei) and the neurons that respond to it.
somatic tinnitus Subjective tinnitus in which the onset can be attributed to some injury of the head or neck.
somatosound Body sound.
spontaneous activity Neuronal activity not preceded by a stimulus.
spontaneous otoacoustic emissions Otoacoustic emissions not preceded by an acoustic stimulus.
subjective tinnitus Tinnitus that can be heard only by the individual experiencing it.
synchrony Simultaneous increased neural activity from two or more sources.
temporary threshold shift Reversible hearing loss resulting from exposure to intense sound.
timbre The psychophysical quality of a sound that depends on the spectrum of the sound's frequencies.
trigeminal ganglion Sensory neuronal center of the trigeminal nerve located inside the base of the skull.
trigeminal nuclei Spinal and brainstem sensory neuronal centers of the trigeminal nerve.

3.18.1 Definition of Tinnitus

Tinnitus is the perception of a sound in the absence of an external acoustic stimulus. Tinnitus may be categorized as objective or subjective. Objective tinnitus is produced by an internal acoustic stimulus or somatosound (body sound) activating the inner ear by air conduction or bone conduction of the sound. Somatosounds include vibrations produced by muscular contractions (myoclonus) and vascular pulsations. Another form of objective tinnitus results from spontaneous otoacoustic emissions from the inner ear that can often be heard by the individual producing them. Objective tinnitus can be heard by another person with a stethescope or by electronic monitoring. Subjective tinnitus can be heard only by the individual experiencing it and has no acoustic source and, therefore, no activation of the inner ear. In current usage, the term tinnitus refers to subjective tinnitus, and somatosound refers to objective tinnitus. Pulsatile tinnitus is a variety of objective tinnitus that is synchronous with the heartbeat and due to vascular compression, malformations or tumors. Somatic tinnitus refers to subjective tinnitus in which the onset can be attributed to some somatic injury in the head and neck region and may or may not be associated with hearing impairment.

3.18.2 Clinical Overview

Nearly everyone occasionally experiences brief subjective tinnitus of a ringing quality lasting seconds or minutes. Indeed, many individuals experience tinnitus in a soundproof booth, and most experience tinnitus in near-perfect silence such as in an anechoic chamber (Heller, M. and Bergman, M., 1953). A more common experience is the transient ringing tinnitus that follows brief exposure to intense sound that is capable of producing a temporary threshold shift but not permanent hearing impairment. Likewise, ingestion of large amounts of salicylate or quinine may result in transient tinnitus.

Most clinical concern is with chronic tinnitus that may be frequently or continuously present. The vast majority of chronic tinnitus is caused by exposure to loud noise, but chronic tinnitus may be associated with any conductive or sensorineural hearing impairment. Among conductive hearing losses causing tinnitus are obstruction of the external auditory canal and middle-ear abnormalities including otitis media and effusion, tympanic membrane perforation, tympanosclerosis and ossicular discontinuity and fixation as in otosclerosis. In addition to noise exposure, tinnitus associated with sensorineural hearing impairment results from genetic mutations, ototoxic drugs, inner-ear infections, head injury, and aging.

Tinnitus is described as ringing, buzzing, hissing, and like the sounds of insects or, in Meniere's disease, as a low-pitched roaring. Tinnitus fluctuates in pitch, loudness and timbre in many individuals. Nevertheless, tinnitus can often be matched audiometrically for frequency and intensity. Most commonly, the pitch of tinnitus is matched to pure tones and the central frequency is found to be at 3 kHz or above. The results are often variable, and octave errors are common. The match frequency tends to correlate with the severity of the sensorineural hearing loss. Individuals with tinnitus below 1500 Hz tend to have more severe hearing losses, especially in the low frequencies, than do individuals with high-pitched tinnitus. Once the central frequency is determined, the intensity of the tinnitus can be matched and is usually about 10 dB above the threshold of hearing at that frequency. Tinnitus can often be modulated by somatic factors such as head and neck movements or clenching of the teeth.

Many people, perhaps 30 million in the United States, experience chronic tinnitus. Most of these individuals do not appear to be greatly bothered by their tinnitus. They seek professional care for diagnosis to determine if the tinnitus is a warning of an impending serious disease, such as a brain tumor, or impending deafness. Once the diagnostic evaluation is completed, most of them accept the reassurance and do not appear to be highly motivated to seek a cure for their tinnitus. Perhaps, only 10% of individuals experiencing tinnitus suffer from it in that it interferes with their occupational or social activities. They describe their tinnitus as annoying, irritating, intrusive, and distracting. It affects their sleep (getting to sleep and staying asleep), concentration, ability to understand conversation, and ability to relax and enjoy life. Many who suffer from tinnitus have anxiety and depression.

3.18.3 Associated Decreased Sound Tolerance

Individuals with tinnitus often have decreased sound tolerance in the form of hyperacusis and misophonia (Jastreboff, P. and Jastreboff, M., 2004a). Individuals with hyperacusis experience physical discomfort from exposure to low or moderate sound intensity.

They express a negative attitude toward sound and avoid sound. The discomfort depends on the spectrum and intensity of the sound. According to the theoretical concept of Jastreboff P. and Jastreboff M. (2004a) , hyperacusis is believed to result from an abnormally high level of neuronal activity in the auditory pathways due to excessive amplification of acoustically evoked neuronal signals. The limbic and autonomic nervous systems are activated due to the abnormal activity in the auditory pathways. Individuals with misophonia have a strong dislike or hate of sound and consequently avoid sound. The reaction depends on the individual's previous experience with a given sound, the context of the sound and the individual's psychological profile. According to the Jastreboff and Jastreboff hypothesis, misophonia is believed to be an abnormally strong reaction of the limbic and autonomic nervous systems to sound without abnormally high activation of the auditory system. Physiologic evidence for these appealing concepts has not so far been obtained. Frequently, hyperacusis and misophonia coexist.

3.18.4 Epidemiology of Tinnitus

The incidence of new cases of bothersome tinnitus in the age group 48–92 years is roughly 1.14% per year (Nondahl, D., Cruickshanks, K., Wiley T., *et al.*, 2002). The incidence appears to increase with age. Parenthetically, bothersome tinnitus is a term that has been used in interview surveys and should not be considered equivalent to suffering from tinnitus. The prevalence of tinnitus in individuals 20 years of age or greater is 10–15% in large national surveys. The age trend increases up to age 60–69 years, remains almost as high between 70 and 79 years and declines in the oldest age group, 80 years or greater (Hoffman, H. and Reed, G., 2004). Age-specific prevalence of tinnitus differs from the prevalence of hearing impairment's nearly exponential increase with age. Based on the 1990 Hearing Supplement to the National Health Interview Survey, Hoffman and Reed estimate that there were nearly 15 million adults with bothersome tinnitus in the United States (Hoffman, H. and Reed, G., 2004).

Among risk factors or associated characteristics for tinnitus are advancing age, male sex, less than a high school education, lower income, rural residence, occupational noise exposure, general health status reported as fair or poor, higher body mass index and hearing loss reported as of moderate or higher degree (Hoffman, H. and Reed, G., 2004). Men are 50% more likely than women to have chronic or bothersome tinnitus (Hoffman, H. and Reed, G., 2004). Although the age trends for tinnitus for men and women are similar in the 1994–95 United States National Health Interview Survey Disability Supplement, beginning at approximately age 30 years the prevalence of tinnitus in men rises more steeply and remains higher until age 85 years. There is a clear separation of men and women in prevalence from the age of 40–79 years probably due to men being more likely to be exposed to intense environmental noise from occupational or leisure (hunting) activities (Hoffman, H. and Reed, G., 2004). Strong associations between tinnitus and occupational noise exposure have previously been demonstrated.

With multivariate analysis, there is still a significantly greater risk of tinnitus for men aged 45–54 years; however, for men aged 75–84 years and 85+ years, there is a significant reduced risk of tinnitus (Hoffman, H. and Reed, G., 2004). Aging in men appears protective against tinnitus for reasons that are unclear.

There is a steady increase in risk of tinnitus with increasing hearing impairment. In addressing the issue of the role of aging once there is proper accounting for the hearing loss, Hoffman H. and Reed G. (2004) find that there is a lower prevalence of tinnitus as age cohort increases for any given level of hearing impairment.

Non-Hispanic whites are more likely than other races and ethnic groups to report chronic tinnitus although race and ethnicity do not appear to be strongly related to the risk of tinnitus in the United States (Hoffman, H. and Reed, G., 2004).

The odds ratio for chronic tinnitus is 50% greater in the West than in the Northeast of the United States (Hoffman, H. and Reed, G., 2004). The reason for this is uncertain but may be related to hunting and other forms of shooting.

Management or administrative and technical or sales occupational groups have a reduced risk of chronic tinnitus, and skilled or unskilled workers have a greater risk of chronic tinnitus. Prior military service carries a greater risk of chronic tinnitus (Hoffman, H. and Reed, G., 2004). Cigarette smoking increases the risk of bothersome tinnitus, whereas moderate drinking of alcohol of one drink per day or less reduces the risk.

There is a twofold increase in the risk of bothersome tinnitus for male and female siblings of individuals with

tinnitus, which suggests a familial association due to shared environmental factors or a genetic basis (Hoffman, H. and Reed, G., 2004).

3.18.5 Animal Models of Tinnitus

In 1988, Jastreboff and colleagues published their findings of conditioned suppression in rats that are trained to respond to silence and that fail to do so if tinnitus is present (Jastreboff, P. *et al.*, 1988). Tinnitus is induced with sodium salicylate, and the magnitude of the response is dose related. Extinction of the reflex occurs after several days. A rough estimate of intensity has been obtained. The results depend on group averages and do not yield information on individual subjects. Tinnitus in this model has also been induced with intense sound. It has been used to measure the therapeutic effectiveness of Ginkgo biloba in rats.

Jastreboff's animal model is a seminal contribution and has been followed by several others. Bauer and colleagues developed a passive avoidance procedure that allows determination of intense sound-induced tinnitus in rats over extended periods of time (Bauer, C. *et al.*, 1999). Bauer C. and Brozoski T. (2001) have used this procedure to measure the therapeutic effectiveness of gabapentin for tinnitus in rats. Heffner H. and Harrington I. (2002) used a somewhat similar procedure in hamsters. More recently, Heffner H. and Koay G. (2005) has, after training hamsters to respond to the direction from which sound is presented, induced unilateral tinnitus with intense sound and demonstrated that in the absence of acoustic stimulation the hamsters respond as if sound had been presented to the ear with tinnitus. This procedure allows gathering data from individual subjects without concern for the effect of hearing loss produced by the exposure to intense sound. However, the testing is limited because the testing is carried out to extinction.

3.18.6 Neurophysiologic Model of Tinnitus

The vast majority of tinnitus is associated with sensory hearing impairment. Although the initiation of tinnitus results from a lesion in the inner ear, once tinnitus is established it seems to take on a life of its own in the brain. In the individual who suffers from tinnitus, Jastreboff's neurophysiologic model of tinnitus offers the most plausible explanation of the responsible phenomena. Jastreboff P. and Jastreboff M. (2004b) contend that in individuals who suffer from tinnitus, the auditory system plays a minor role. They emphasize the role of the activation of the limbic and autonomic nervous systems, particularly the sympathetic part of the autonomic nervous system. When tinnitus-related neuronal activity is temporally associated with cognitively induced or high-stress-induced activation of the limbic and autonomic nervous systems, a conditioned reflex is established. Initially, this activation provides reinforcement for the reflex. Later the tinnitus signal activates the limbic and autonomic nervous systems without adverse cognition or stress. Physiologic and behavioral reactions caused by the activation of the limbic and autonomic nervous systems provide reinforcement of the reflex, and a vicious circle occurs. According to Jastreboff and Jastreboff, tinnitus is classified by the individual as important or not and with a positive or negative connotation. Reinforcement increases with greater importance, and the type of reaction is determined by the connotation. Continuous tinnitus-related neuronal activity and the reaction due to activation of the limbic and autonomic nervous systems preclude extinction of the reflex.

3.18.7 Theoretical Mechanisms of and Sites Associated with the Percept of Tinnitus

3.18.7.1 Peripheral Processes Involved in Tinnitus

Nuttall A. *et al.* (2004) recount a possible mechanism in the generation of tinnitus stemming from the edge effect of relatively normal hair cells on the low-frequency side and abnormal or absent hair cells on the high-frequency side of a lesion. They also note other possible peripheral mechanisms of generation of tinnitus including excessive release of neurotransmitter at the inner hair cell-type I afferent synapse, increased cochlear amplification resulting in mechanical noise from motion of the basilar membrane and reduced cochlear amplification decreasing the spontaneous rate in the neurons of the auditory nerve.

Based on correlations between psychoacoustic parameters of tinnitus, particularly pitch matching and localization, and the extent of inner ear damage, Meikle has pointed out that there is an ongoing

dynamic interaction between the inner ear and brain centers in tinnitus (Meikle, M., 1995).

3.18.7.2 Otoacoustic Emissions

Although there is usually no relationship between otoacoustic emissions and tinnitus, Lonsbury-Martin B. and Martin G. (2004). draw attention to a rare type of spontaneous otoacoustic emissions which is audible to the individual with it, much larger and at a higher frequency range than the usual spontaneous otoacoustic emissions and associated with a broad region of abnormal outer hair cells.

3.18.7.3 Neural Correlates of Tinnitus

Tinnitus induced with intense sound in animals is associated with increases in neuronal discharge rates in the dorsal cochlear nucleus; inferior colliculus, particularly in its external nucleus; and the primary auditory cortex. It is difficult to know if the hyperactivity is due to tinnitus or the associated hearing loss.

A recurring confounding problem in tinnitus research is that tinnitus is ordinarily associated with hearing impairment. Segregation of the correlates of tinnitus from the consequences of hearing impairment requires the inclusion of a second control group. Since some animals in which tinnitus induction has been attempted develop hearing impairment but no tinnitus, comparing healthy animals, animals with hearing impairment but no tinnitus and animals with hearing impairment and tinnitus improves the validity of the research. Clinical research on the mechanisms of or the sites associated with the percept of tinnitus is also confounded by this problem, and the solution is to include controls matched for hearing impairment who do not experience tinnitus.

Kaltenbach J. *et al.* (2004) suggest that hearing loss and tinnitus involve different mechanisms and a different time course in that the hyperactivity in the dorsal cochlear nucleus appears several days after the onset of the hearing loss following exposure to intense sound. They speculate that sound percepts of tinnitus are due to increased spontaneous activity and perhaps increased synchrony in the auditory cortex (Eggermont, J., 2004) and that the pitches of those percepts depend on characteristic frequencies that predominate in the expanded and reorganized region of the cortex as occurs in plasticity.

On the other hand, Eggermont points out that, in the tonotopically organized lemniscal pathway of the auditory system, a reduction in spontaneous activity is the rule in response to tinnitus-inducing agents (salicylate, quinine, and intense sound). Increased spontaneous activity has been found in the multimodal (auditory and somatosensory) dorsal cochlear nucleus and the nonlemniscal external nucleus of the inferior colliculus (Eggermont, J., 2004). Although it is generally assumed that the initiation, generation, and maintenance of tinnitus occurs as ascending phenomena in the auditory pathway, Eggermont calls attention to the temporal relationship of increased activity in the auditory cortex in hours and in the dorsal cochlear nucleus in days after exposure to intense sound and suggests that the initiation of increased spontaneous activity may occur in the auditory cortex first and secondarily in the dorsal cochlear nucleus.

3.18.7.4 Cortical Plasticity

Schreiner C. and Cheung S. (2004) point out that it is difficult to separate plastic changes due to hearing loss from those due to tinnitus. They suggest that acvtivity-dependent plasticity may be involved in the development of tinnitus. Stroke and trauma to the auditory cortex initiate injury-induced plasticity that may account for rare forms of tinnitus without peripheral injury.

3.18.7.5 Somatosensory Nuclei in Tinnitus

Somatic tinnitus apparently depends on the somatosensory innervation of the cochlear nucleus, superior olivary complex, and inferior colliculus. Stimulation of the trigeminal ganglion or nuclei causes excitation or inhibition of the neurons of the cochlear nucleus and inferior colliculus. Shore S. (2004) has demonstrated integration of acoustic and somatosensory stimuli causing an increased or decreased response in the cochlear nucleus or inferior colliculus that is greater or less than the sum of the parts. This integration could play a role in the generation of somatic tinnitus.

3.18.8 Evaluation of the Individual with Tinnitus

The neurotologic evaluation of the individual with tinnitus is similar to the evaluation of the individual with hearing impairment. The audiologic assessment includes matching of the pitch and loudness of the

tinnitus as well as estimation of the maskability of the tinnitus. Several tinnitus questionnaires have been developed and validated and serve as intake and outcome measures for the severity of the distress caused by tinnitus.

Brain imaging of tinnitus with functional magnetic resonance imaging and positron emission tomography is in the early stage of development. Already objective evidence of tinnitus has been demonstrated in the inferior colliculus and auditory cortex (Lockwood, A. *et al*., 1998; Melcher, J. *et al*., 2000). Brain imaging is likely to provide a level of objective evidence of tinnitus not previously attained.

3.18.9 Treatment of the Individual with Tinnitus

Antidepressive drugs are important therapy for individuals who suffer from tinnitus and have depression or insomnia and perhaps for those without depression. Hearing aids are an essential part of tinnitus management. Tinnitus retraining therapy and other psychological methods of treatment are effective for individuals who suffer from tinnitus (Jastreboff, P. and Jastreboff, M., 2003). Electrical suppression of tinnitus with high-rate ($5000\,s^{-1}$) pulse trains delivered to the inner ear has been demonstrated to occur without producing an auditory percept but continues to be experimental (Rubinstein, J. *et al*., 2003).

The neuromodulatory systems are sufficiently well understood to be directly or indirectly manipulated in the treatment for tinnitus with emotional associations of fear, depression, or decreased sound tolerance (Schreiner, C. and Cheung S., 2004). Since the cholinergic system is stimulus feature directed and the amygdala is critical in emotional processing, the cholinergic system may be helpful in therapy for emotionally laden tinnitus (Schreiner, C. and Cheung S., 2004). Drugs influencing the serotonin system, such as the selective serotonin reuptake inhibitors, may reduce the adverse aspects of tinnitus (Robinson, S. *et al*., 2005).

Because of the large placebo effect in individuals with tinnitus, randomized, placebo-controlled, double-masked clinical trials are required to evaluate therapy for tinnitus (Dobie, R., 1999). Furthermore, clinical trials should be limited to subjects who suffer from tinnitus as determined by a criterion score on validated tinnitus questionnaires.

Schreiner C. and Cheung S. (2004) propose that behavioral therapy enhanced with pharmacotherapy may be the most promising approach to tinnitus treatment.

Glossary

gating current A brief electrical current that precedes the opening and closing of voltage-gated ion channels. It results from the movement of a charged voltage sensor.

hydrophobicity analysis A method to identify possible/partial structural domains of proteins according to the hydrophobicity or hydrophilicity of the amino acids. A quantitative measure of the hydrophobicity of each amino acid is plotted against its order in the proteins sequence.

cystic fibrosis transmembrane conductance regulator (CFTR) A chloride channel, member of the superfamily of ATP-binding cassette (ABC) transporter proteins.

yeast-two-hybrid assay A molecular biological method to identify the direct interaction of two proteins, which is based on protein–protein association in living yeast cells.

nonlinear capacitance Voltage-dependent component of the membrane capacitance that results from the reversible translocation of an electrically charged particle through the membrane (also see 'gating current').

lock-in technique Phase-sensitive detection method that extracts a signal from a sinusoidal carrier wave at a certain phase angle.

3.19.1 Introduction: Outer Hair Cell Electromotility and Prestin

The cylindrical outer hair cells (OHCs) change their length in response to variation of the membrane potential; depolarization induces contraction of up to 4% and hyperpolarization leads to elongation. Unlike other cellular motile processes that depend on molecular motors acting on cytoskeletal elements, electromotility turns out to be an intrinsic membrane process residing in the lateral plasma membrane of the epithelial OHCs (reviewed by Holley, M. C., 1996). As such, it is not driven by adenosine triphosphate (ATP) hydrolysis, or triggered by ionic currents or rise in cytosolic Ca^{2+} but directly depends on the membrane potential. Analysis of the movements indicated that independent elementary motors distributed along the lateral membrane of the OHC generate electromotility (Dallos, P. *et al.*, 1991). Indeed, electromotility can be observed after removal of the entire cytoskeleton by proteolytic digestion and even in isolated patches of the OHC

membrane. This membrane motor mechanism is supported by an extremely high density of intramembrane particles in the lateral membrane of OHCs that can be visualized with electron-microscopic techniques. These particles are thought to be individual motor proteins. Central to the understanding of how distributed elementary motors in the membrane may generate movement is the observation that electromotility has an electrical signature: it is inextricably associated with the transfer of electrical charge across the membrane that can be measured as a gating current at the onset of a voltage jump (Dallos, P. and Fakler, B., 2002). Charge transfer and motility share the same voltage dependence, suggesting that the former results from the translocation of a charged particle (voltage sensor) within a membrane motor protein, which in turn directly triggers a force-producing conformational change.

In 2000, Dallos and colleagues used a subtractive cDNA library to isolate a cDNA encoding a protein present in OHCs but not in nonmotile inner hair cells and termed it prestin (Zheng, J. *et al.*, 2000). Prestin is selectively expressed in the inner ear (Zheng, J. *et al.*, 2000; Liu, X. Z. *et al.*, 2003), and specific antibodies directed against prestin label the lateral plasma membrane of OHCs exclusively and strongly (Belyantseva, I. A. *et al.*, 2000; Zheng, J. *et al.*, 2001). When expressed heterologously in culture cells prestin reproduces all the hallmarks of OHC electromotility. In particular, cells expressing prestin generate movement and force in response to electrical stimulation and produce charge movement, the electrical signature of electromotility (Zheng, J. *et al.*, 2000; Ludwig, J. *et al.*, 2001; Santos-Sacchi, J. *et al.*, 2001). Vice versa, OHCs from prestin knockout mice entirely lack electromotility (Liberman, M. C. *et al.*, 2002). Since it is both necessary and sufficient for electromotility, prestin is unquestionably the OHC membrane motor, or, at least, its core component.

3.19.2 Molecular Structure of Prestin

Prestin cDNAs from several rodents as well as from humans (Zheng, J. *et al.*, 2000; Ludwig, J. *et al.*, 2001; Liu, X. Z. *et al.*, 2003; Zheng, J. *et al.*, 2003) are now available, all coding for a protein of 744 amino acids (aa) with a predicted molecular weight of about 81 kDa. The aa sequence is highly conserved among mammalian species, showing sequence identity of 95% between mouse and human prestin with most exchanges occurring in the distal C- and N-termini. The prestin gene is localized on chromosomes 5 and 7 (location 7q22.1) in mice (Zheng, J. *et al.*, 2003) and humans (Liu, X. Z. *et al.*, 2003), respectively, and comprises 20 (mice) and 21 (humans) exons. Alternative shorter splice isoforms have been detected in the human fetal cochlea; however, their expression level is low and their functional role has not been examined (Liu, X. Z. *et al.*, 2003).

Prestin is the fifth mammalian member of the SLC26 family of anion transporters, and is therefore designated SLC26A5 (Zheng, J. *et al.*, 2000). Including prestin, the SLC26 family comprises 10 members in mammals and many homologs have been identified throughout eukaryotic and bacterial phyla (Mount, D. B. and Romero, M. F., 2004). The mammalian family members show aa sequence identities to prestin between 22% and 40% with SLC26A6 being the closest homolog.

Nonmammalian homologs of prestin have been identified in chicken, zebrafish, and drosophila (Weber, T. *et al.*, 2003; Schaechinger, T. J. and Oliver, D., 2007). The chicken and zebrafish molecules are clearly orthologs of mammalian prestin (with 58% and 52% aa sequence identity to rat prestin, respectively) while the insect homolog is more distantly related. Strikingly, these homologs are expressed in inner ear hair cells in zebrafish (Albert, J. T. *et al.*, 2007) and in mechanosensory organs of flies (Weber, T. *et al.*, 2003). However, they have no detectable electromotile properties (Albert, J. T. *et al.*, 2007), but are electrogenic anion transporters (Schaechinger, T. J. and Oliver, D., 2007). Thus, it seems possible that the molecular machinery of electromotility evolved from an ion transport mechanism present in the mechanosensory cells of nonmammalian ears.

Very similar to other SLC26 family members, hydrophobicity analysis of the aa sequence of prestin shows hydrophilic N- and C-termini and a hydrophobic core region with numerous hydrophobic stretches, indicative of transmembrane domains (Figure 1). The membrane topology of prestin is, as yet, incompletely resolved. Clearly, both N- and C-termini are located intracellularly since terminal epitopes are accessible to specific antibodies only in permeabilized cells (Ludwig, J. *et al.*, 2001; Zheng, J. *et al.*, 2001). This reduces the possible transmembrane topologies to those with an even number of complete membrane spans, possibly 10 or 12. Prestin contains two N-glycosylation consensus sites at positions 163 and 166 that are conserved among SLC26 family members. Interference with glycosylation shifted

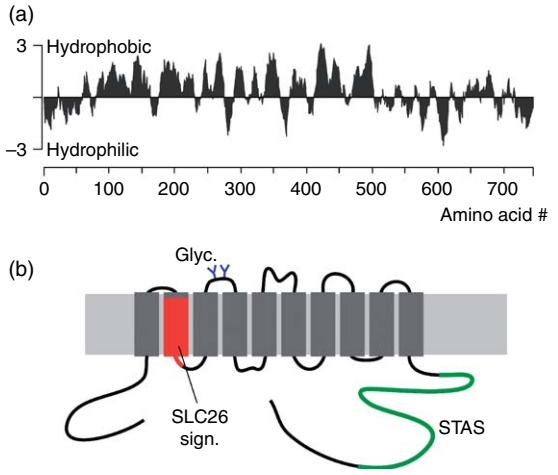

Figure 1 Molecular structure of prestin. a, Hydrophobicity plot of prestin, obtained with the Kyte-and-Doolittle algorithm. b, Hypothetic membrane topology of prestin. The full topology has not been determined experimentally and prediction algorithms yield divergent results (Zheng, J. *et al.*, 2001). Alternative models have been proposed (Oliver, D. *et al.*, 2001; Deak, L. *et al.*, 2005; Navaratnam, D. *et al.*, 2005). Structural motifs are outlined: STAS-domain (STAS, green); N-glycosylation sites (Oliver, D. *et al.*, 2001; Deak, L. *et al.*, 2005) (Glyc., blue); SLC26 transporter signature domain (SLC26 sign., red).

the apparent molecular weight of prestin and slightly affected its electrical properties (Matsuda, K. *et al.*, 2004), suggesting actual glycosylation at this site and extracellular localization of the short hydrophilic sequence stretch flanking this site, in agreement with preliminary epitope accessibility studies (Oliver, D. *et al.*, 2001). Unfortunately, more detailed topological information is currently not available for any other member of the SLC26 family. A preliminary suggestion for prestin's topology based on the above information and on hydrophobicity is shown in Figure 1. However, the actual membrane topology may be more complicated as it may contain partial membrane spans (Deak, L. *et al.*, 2005).

Prestin contains two highly conserved sequence stretches, one termed SLC26 transporters signature (Prosite entry PS01130), defined as a region highly conserved throughout family members, and a sulfate transporter and antisigma antagonists (STAS) domain (Prosite entry PS50801; Zheng, J. *et al.*, 2000; Mount, D. B. and Romero, M. F., 2004). The SLC26 signature motif approximately corresponds to the second putative transmembrane helix; its functional relevance is currently not known. The C-terminal STAS domain of the prestin relatives SLC26A3 and A6 is involved in the interaction between the SLC26 transporter and the cystic fibrosis transmembrane conductance regulator (CFTR) chloride channel. Here, the STAS domain appears to directly activate CFTR (Ko, S. B. *et al.*, 2004). A functional interaction of prestin with CFTR was also reported recently (Zheng, J. *et al.*, 2005).

Moreover, prestin harbors several potential protein phosphorylation sites, including consensus sites for protein kinase A (PKA), protein kinase G (PKG), protein kinase C (PKC), and protein kinase CK2. OHC electromotility is modulated by cGMP-dependent phosphorylation (Sziklai, I. *et al.*, 2001). Activation of PKG by cyclic guanosine monophosphate (cGMP) analogs indeed modified functional properties of recombinant prestin, suggesting phosphorylation at two PKG sites (Deak, L. *et al.*, 2005). In native OHCs, prestin's voltage dependence changes during postnatal development (Oliver, D. and Fakler, B., 1999) and is affected by agents that interfere with phosphorylation (Frolenkov, G. I. *et al.*, 2000), both consistent with a role for phosphorylation in the regulation of prestin's function.

Electron microscopy indicates that the OHC membrane may be mechanically linked to the underlying actin cytoskeleton (Holley, M. C., 1996), possibly in order to translate the force generated by the elementary motors into a macroscopic movement of the cell body. Such coupling suggests protein–protein interactions involving prestin. As yet, the promyelocytic leukemia zinc finger protein (PLZF) has been suggested as a direct interaction partner of prestin based on yeast-two-hybrid assays (Nagy, I. *et al.*, 2005). Moreover, given the size of particles in the OHC membrane (diameter $\approx$ 10 nm; Holley, M. C., 1996) it seems conceivable that each unitary motor is either an oligomer of prestin or may contain accessory proteins. Biochemical data (Zheng, J. *et al*, 2006) and fluorescence resonance energy transfer measurements (Navaratnam, D. *et al.*, 2005) are consistent with the oligomeric assembly of prestin.

3.19.3 Functional Properties of Prestin

As noted above, prestin can account for all mechanical and electrical hallmarks of OHC electromotility. When transfected into culture cells it generates voltage-dependent mechanical movement and electrical charge transfer (Zheng, J. *et al.*, 2000; Ludwig, J. *et al.*, 2001).

3.19.3.1 Electromechanical Activity

The electromechanical activity of prestin has been measured in cells transfected with gerbil and rat prestin using the microchamber method, where an isolated cell is partially drawn into a tightly fitting glass capillary (Holley, M. C., 1996; Zheng, J. *et al.*, 2000). Voltage commands applied across the cell depolarize and hyperpolarize the excluded and included segments of the cell's membrane in opposite polarity. The excluded segment of the cell was shown to move according to a sinusoidal voltage stimulus with amplitudes of up to 0.2 μm if prestin was present (Zheng, J. *et al.*, 2000). Using an atomic-force cantilever of known stiffness, Ludwig J. *et al.* (2001) showed that the excluded segment of prestin-expressing cells indeed generates force when stimulated electrically. The electromotile force resulted from the expression of prestin because it was inhibited by a known blocker of OHC electromotility, salicylate.

3.19.3.2 Charge Transfer

Electrical charge transfer mediated by prestin can be recorded as a gating current in response to a steplike displacement of the membrane voltage. On returning to the initial voltage, a current of the opposite sign but carrying the same amount of charge is observed. This reversibility of charge transfer and its high speed allow monitoring of it as a voltage-dependent capacitance (usually termed nonlinear capacitance, NLC; for details, see Dallos, P. and Fakler, B., 2002). Since membrane capacitance can be recorded with standard lock-in patch-clamp techniques, NLC is often used to characterize the properties of prestin. While control cells do not exhibit any appreciable NLC, expression of prestin is sufficient to produce NLC with properties equivalent to that seen in OHCs (Ludwig, J. *et al.*, 2001; Santos-Sacchi, J. *et al.*, 2001).

The specific voltage dependence and kinetics of both force generation and charge transfer have important implications for the physiological function of prestin in hearing and for understanding the underlying molecular mechanism. These properties have been studied extensively using the native protein in OHCs and have subsequently been confirmed with recombinant prestin.

3.19.3.3 Voltage Dependence

Both length changes and electrical charge transfer exhibit an identical sigmoidal dependence on membrane potential that saturates for very negative and positive voltages (Santos-Sacchi, J., 1991; Santos-Sacchi, J., 1992; Figure 2). Concerning motility, the OHC is short at depolarized and elongated at hyperpolarized potentials. Notably, the same polarity was observed in prestin-transfected cells (Ludwig, J. *et al.*, 2001). The sigmoidal voltage dependence can be accurately modeled by a first-order Boltzmann function, indicating that the underlying process is the voltage-dependent redistribution of molecules between two states (see Section 3.19.4.1). Accordingly, the derivative of charge transfer, NLC, is bell-shaped and corresponds to the derivative of a Boltzmann function (Santos-Sacchi, J., 1991; Figure 2). Fitting motility or charge movement with a Boltzmann function yields two main parameters that quantitatively characterize prestin's voltage dependence: (1) the slope (steepness) of the voltage dependence and (2) $V_{1/2}$, defined as the voltage at which half of the molecules reside in either conformation. The Boltzmann slope determined from recordings of electromotility or NLC of native or recombinant prestin is about 30 mV, which translates into the transport of about 0.8 elementary electrical

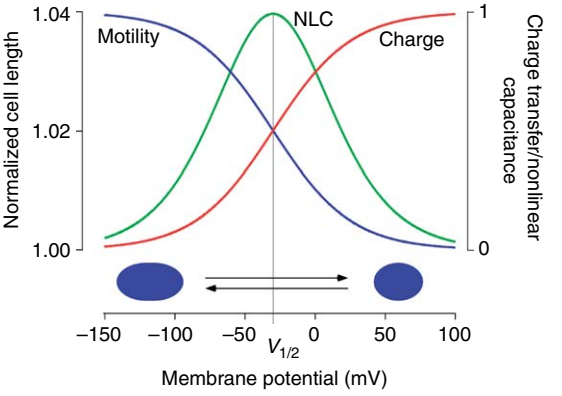

Figure 2 The characteristic mechanical and electrophysiological behavior of prestin. OHC length (blue) shortens with depolarization of the membrane potential in a saturating manner according to a first-order Boltzmann function. The underlying area change in the individual motor proteins is depicted schematically. Electromotility is coupled to electrical charge movement across the membrane (red). The amount of charge flowing for any given voltage change follows the same sigmoidal voltage dependence as motility. Charge movement can also be recorded as a voltage-dependent capacitance (nonlinear capacitance (NLC), green) that is the derivative of charge and thus has a bell-shaped voltage dependence.

charges through the whole transmembrane electrical field (see Section 3.19.4.1). $V_{1/2}$ is important because it characterizes the voltage of the highest electromechanical gain, that is, largest displacement of the cell for a given voltage change (Santos-Sacchi, J., 1992). $V_{1/2}$ also denotes the voltage at maximum NLC and in mature OHCs is typically around −30 mV (Santos-Sacchi, J., 1992; Kakehata, S. and Santos-Sacchi, J., 1995; Oliver, D. and Fakler, B., 1999). In contrast, heterologously expressed prestin yields a $V_{1/2}$ of ∼−70 mV, substantially hyperpolarized compared to the OHC (Ludwig, J. *et al.*, 2001; Santos-Sacchi, J. *et al.*, 2001). However, $V_{1/2}$ in OHCs can be shifted by various manipulations including agents that affect phosphorylation (Frolenkov, G. I. *et al.*, 2000) and is also more negative in immature OHCs (∼−90 mV; Oliver, D. and Fakler, B., 1999), suggesting that this difference in $V_{1/2}$ does not indicate a fundamental distinction between native and recombinant prestin but is more likely a regulatory issue.

3.19.3.4 Kinetics

The kinetics of electromotility and prestin-mediated charge movement are extremely rapid. Electromotility works at microsecond rates and has been measured up to 70 kHz from OHCs (Frank, G. *et al.*, 1999). Force generation by recombinant prestin shows no sign of attenuation up to at least 20 kHz (Ludwig, J. *et al.*, 2001). Electrophysiological measurements of the charge transfer are generally limited in time resolution because of low-pass filtering by the membrane capacitance in conjunction with a series resistance and the speed of the amplifier. However, using recordings from isolated membrane patches that yield high cut-off frequencies, microsecond rates for charge movements have been obtained (Gale, J. E. and Ashmore, J. F., 1997).

3.19.3.5 Pharmacology

Only few inhibitors of prestin-mediated electromotility are known, and none of them appears to act with high specificity. Salicylate reversibly inhibits electromotility at low millimolar concentrations (Kakehata, S. and Santos-Sacchi, J., 1996). This hydrophobic monovalent anion appears to affect prestin's function from the intracellular side by competing with the small inorganic anions that are crucial for mediating the voltage dependence of prestin (Oliver, D. *et al.*, 2001). Trivalent lanthanide ions like gadolinium (Gd^{3+}) that are known to block a variety of ion channels with little selectivity inhibit electromotility reversibly at millimolar concentrations (Kakehata, S. and Santos-Sacchi, J., 1996). The mechanism behind this action is unclear.

3.19.4 The Generation of Force and Nonlinear Capacitance by Prestin: Molecular Mechanisms

3.19.4.1 Biophysical Model

The tight coupling between charge movement and electromotility has led to the formulation of a biophysical model of force generation, the area motor model of electromotility (Dallos, P. *et al.*, 1993; Iwasa, K. H., 1994). In essence, the elementary motor, prestin, can adopt (at least) two conformational states, which occupy different areas in the plane of the membrane. The macroscopic movements that can be observed experimentally thus result from synchronous transitions of large numbers of prestin molecules from an extended to a compact conformation or vice versa. Occupancy of both states is voltage dependent. This voltage dependence requires an electrically charged particle, the voltage sensor that can move across the membrane electrical field to trigger the conformational area change in the protein, in doing so producing the charge transfer. Such a mechanism is analogous to the gating of voltage-dependent ion channels, where movement of the positively charged S4 helix triggers opening of the channel pore and can be observed as a gating current (Dallos, P. and Fakler, B., 2002). This simple two-state model is supported by the finding that charge and mechanics adhere to the same voltage dependence that can be accurately described by a two-state Boltzmann function. Though more complex reaction schemes are certainly possible, most experimental data are well described with this simplest model. Moreover, the tight coupling between conformational reorientation and charge transfer requires that electrical as well as mechanical energy terms should influence the occupation of either state. Such electromechanical reciprocity is indeed observed experimentally. Thus, altering the mechanical tension of the membrane shifts the voltage dependence of charge movement and electromotility along the voltage axis (Gale, J. E. and Ashmore, J. F., 1994; Kakehata, S. and Santos-

Sacchi, J., 1995). If tension is increased, $V_{1/2}$ is shifted to more positive potentials, meaning that more depolarization is necessary to push the prestin molecules into their compact conformation. This tension dependency is not only observed in OHCs, but has been confirmed with recombinant prestin (Ludwig, J. *et al.*, 2001; Santos-Sacchi, J. *et al.*, 2001), indicating that it is not due to the specific hair cell environment of prestin but is an intrinsic property of the molecule. Even more striking, changing membrane tension at a constant voltage should thrust molecules from one to the other conformational state, and consequently result in the reverse transfer of their voltage sensor across the membrane. This has been observed experimentally as an electrical current upon rapid stretching of the OHC membrane (Gale, J. E. and Ashmore, J. F., 1994). Estimates for the area change of a single motor molecule (Dong, X. X. and Iwasa, K. H., 2004) are 1–4 nm^2.

Measurements of OHC stiffness have shown that not only cell length but also axial stiffness is voltage dependent (He, D. Z. *et al.*, 2003). This may mean that prestin contributes significantly to the overall stiffness of the OHC and that the conformational states of prestin may differ in their intrinsic stiffness.

Alternative models for electromotility that involve generation of force by the membrane lipid bilayer have been put forward. In these models, prestin is assumed to provide voltage-dependent changes in dielectric properties of the membrane, which in turn may precipitate altered membrane tension (Zhang, P. C. *et al.*, 2001) or membrane bending (Raphael, R. M. *et al.*, 2000). While these models are based on established biophysical mechanisms, direct experimental evidence to support such an action of prestin is currently lacking.

3.19.4.2 Molecular Mechanisms

According to the biophysical model, the prestin molecule should comprise two principal functional domains, one that senses the membrane potential (voltage sensor) and one or more actuator domains that undergo the major conformational change. Since structural data for prestin or related transporters are currently not available, one basic approach to the underlying molecular mechanisms is to identify regions within the protein that are involved in either process.

So far, the issue of the voltage sensor has been addressed, exploiting the easy experimental accessibility of NLC. Using recombinant prestin or patches excised from the OHC membrane it was demonstrated that NLC depends on the presence of monovalent anions at the intracellular but not the extracellular side of the membrane (Oliver, D. *et al.*, 2001). Removal of the major anion chloride (Cl^-) from the cytoplasmic face of prestin reversibly abolished NLC in excised patches. The amount of NLC varied with the Cl^- concentration in a saturable manner, indicating the binding of Cl^- to prestin with millimolar affinity (dissociation constant (K_d) ~6 mM). Small monovalent anions like other halides, bicarbonate, and nitrate could substitute for Cl^-; in contrast, divalent anions like sulfate did not support NLC. While amplitude and $V_{1/2}$ of the NLC varied with the anion species, the steepness of voltage dependence was constant. However, if larger organic anions such as carboxylic acids were used, the steepness decreased with increasing molecule size, which in terms of the two-state voltage-sensor model translates into a reduced sensor charge or a smaller distance traversed by the sensor. These findings are consistent with the translocation of the anion itself through the electric field and suggest that the anion acts as an extrinsic voltage sensor of prestin (Figure 3(b)). In agreement with this idea, Cl^- removal also abolished electromotility, indicating that the force-producing steps are indeed triggered by the anion–prestin interaction (Oliver, D. *et al.*, 2001). Obviously, this model of anion-translocation nicely fits prestin's membership in an anion transporter family. In fact, it is tempting to hypothesize that the charge-translocation step functionally corresponds to a partial reaction in the anion transport cycle of other SLC26 transporters, which have been shown to mediate anion fluxes (Mount, D. B. and Romero, M. F., 2004).

One caveat to this simple model is that reducing the chloride concentration shifted the voltage dependence to more positive potentials (Oliver, D. and Fakler, B., 2002; Rybalchenko, V. and Santos-Sacchi, J., 2003). In other words, less negative intracellular potential is necessary to push an anion toward the extracellular side at a lower anion concentration – contrary to what is expected for a simple anion translocation. Thus, more complex reaction schemes may underlie the charge transfer and charged protein domains of prestin may contribute to it as well. An alternative model has been suggested in which anions bind to one or more distinct binding sites to allosterically regulate charge translocation

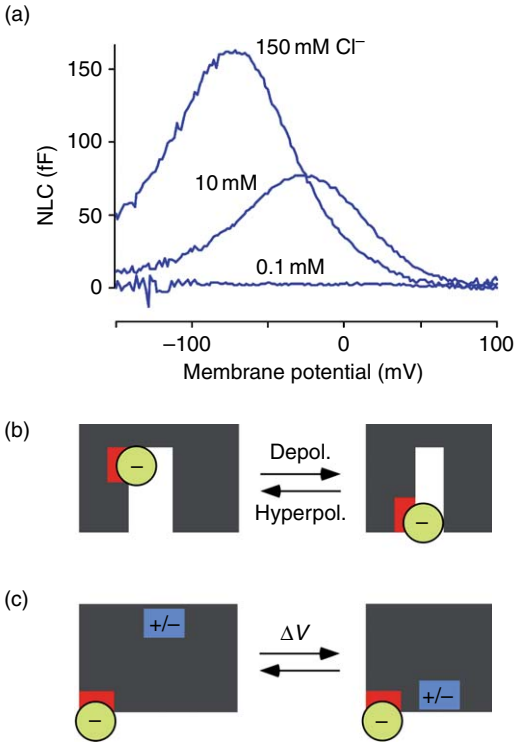

Figure 3 Anion dependence of prestin. a, nonlinear capacitance (NLC) generated by prestin is abolished when intracellular chloride is removed. NLC was measured in an inside–out membrane patch excised from an OHC with the indicated concentrations of Cl^- present at the cytoplasmic side (replacement of Cl^- by SO_4^{2-}). b, Model proposed to explain the anion dependence of prestin (Oliver, D. *et al.*, 2001). After binding to an anion-binding site (red), chloride (or other inorganic anions, yellow) can be translocated through the protein by changes of the membrane potential, and thereby trigger a conformational area change of prestin. The anion thus acts as an extrinsic voltage sensor. c, Alternative model (Rybalchenko, V. and Santos-Sacchi, J., 2003) in which binding of anions allosterically modifies the voltage dependence of prestin, which is mediated by charged residues acting as an intrinsic voltage sensor (blue).

and thus motility (Figure 3(c); Rybalchenko, V. and Santos-Sacchi, J., 2003). In this model, anion binding shifts the position of the NLC curve along the voltage axis. However, such a model predicts two populations of molecules either without or with Cl^- bound that differ in their voltage dependence, which is not observed experimentally (Oliver, D. *et al.*, 2001; Rybalchenko, V. and Santos-Sacchi, J., 2003).

In any case, the essential role of anions for prestin's function directly provokes the question about the molecular identity of the anion binding site. Recent structure–function studies have begun to address this issue. Mutational neutralization of charged aa residues present in prestin but not in the homologous protein SLC26A6 (which does not show charge movement) shifted NLC without abolishing it, suggesting rather an electrostatic effect of these residues on putative anion translocation than a direct involvement in anion binding (Oliver, D. *et al.*, 2001). Recently, mutations in a sequence stretch with similarity to anion coordination sites identified in a bacterial CLC chloride transporter were reported to abolish charge movement (Navaratnam, D. *et al.*, 2005), providing an exciting starting point for the identification of functional domains in prestin. However, due to the tight coupling of charge translocation and molecular motion any mutation that inhibits the conformational change may also arrest charge movement. Mutations that abolish NLC may therefore impair either anion binding, voltage sensor translocation, or the coupled conformational change.

3.19.5 Future Directions

Perhaps the most exciting questions for future research center around the molecular mechanisms of prestin's function. Does the NLC indeed result from physical translocation of anions through the electrical field; alternatively, how much of the sensor charge is supplied by movable residues of the protein? What is the anion-binding domain? And how does the sensor translocation subsequently trigger a gross conformational rearrangement that can even generate macroscopic cellular forces? Which are the domains of prestin that actually move upon changes in membrane voltage? Answers to these questions may arise from examining the mechanistic relationship between electromotility and the electrogenic anion exchange function of prestin's closest homologs (Schaechinger, T. J. and Oliver, D., 2007).

Thus, progress in understanding the molecular basis of electromotility may unexpectedly prove extremely helpful for understanding the currently completely unresolved mechanism of anion transport by other SLC26 transporters, whose essential roles in ion transport in many organs we are just beginning to appreciate (Mount, D. B. and Romero, M. F., 2004).

3.20.1 Introduction

Sensory processing in the cochlea is initiated when the hair cells respond to excitation by generating receptor potentials. Sensory transduction takes place in the organ of Corti, a strip of sensory epithelium consisting of a single row of inner hair cells (IHCs) and three rows of outer hair cells (OHCs) sandwiched between two extracellular matrices, the basilar membrane (BM), and tectorial membrane (TM) (Lim, D. J., 1986). Altogether, these structures comprise the cochlear partition. Hair cells are excited through sound-induced vibrations of the BM and the resultant reactions of their hair bundles with the overlying TM (ter Kuile, E., 1900; Davis, H., 1958; Allen, J. B., 1980; Zwislocki, J. J., 1980; Dallos, P., 2003; Legan, P. K. *et al.*, 2005; Chan, D. K. and Hudspeth, A. J., 2005; Nowotny, M. and Gummer, A. W., 2006; Fridberger, A. *et al.*, 2006) (Figure 1). IHCs, however, share a division of labor with the OHCs; OHCs are sensory-effector cells that both detect and influence mechanical interactions between the TM and the reticular lamina (RL) of the organ of Corti (Brownell, W. E. *et al.*, 1985; Mammano, F. and Ashmore, J. F., 1993; Dallos, P., 1992; Dallos, P. and Corey, M. E., 1991). They are most effective at exerting electromechanical feedback to the cochlear partition at frequencies close to the characteristic frequency (CF) of their location on the BM (Geisler, C. D., 1998). Their role is to amplify responses to low-level sounds and compress responses to high-level sounds (Geisler, C. D., 1998; Robles, L. and Ruggero, M. A., 2001). They are therefore instrumental in

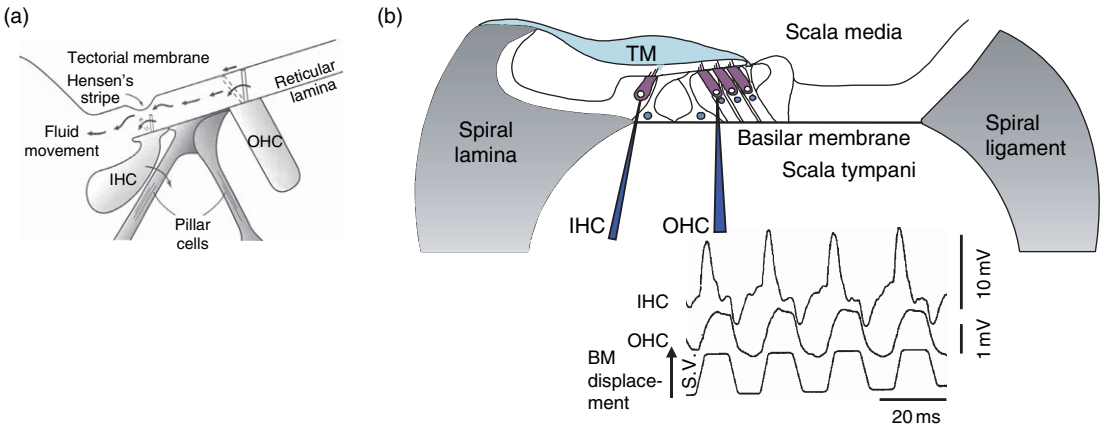

Figure 1 IHCs respond to the velocity and OHCs to the displacement of the BM. (a) OHC hair bundles are attached to the TM and thus OHCs are able to influence the BM movements. IHC hair bundles are coupled by viscous drag and respond passively to the cochlear partition's vibrations. (b) IHC receptor potentials (upper trace) recorded from the basal turn of a guinea-pig cochlea phase lead OHC responses (middle trace) recorded just outside the IHC in response to a 52 kHz, 89 dB SPL trapezoidal acoustic stimulus (lower trace). (a) Reproduced from figure 6.8 of Geisler, C. D. 1998. From Sound to Synapse. Oxford University Press. (b) From figure 1 of Sellick, P. M. and Russell, I. J. 1980. The responses of IHCs to basilar membrane velocity during low frequency auditory stimulation in the guinea pig cochlea. Hear. Res. 2, 439–446.

determining the exquisite sensitivity and frequency tuning of the cochlea and they define the enormous dynamic range of the auditory system. IHCs appear to be purely sensory, their hair bundles responding to the resultant interactions between the TM and RL (Dallos, P. *et al*., 1972; Russell, I. J. and Sellick, P. M., 1978), and their synapses transforming and transmitting the resulting receptor potentials to the afferent fibers, which conduct auditory responses in trains of nerve impulses to the hindbrain nuclei (Spoendlin, H., 1985). OHCs also, presumably, transmit their responses to the type II afferent fibers, although what these responses look like and their purpose remain mysteries (Robertson, D. and Gummer, M., 1985; Robertson, D. *et al*., 1999).

Their roles in cochlear sensory processing being different from each other, IHCs and OHCs thus have different design briefs. IHCs are designed to detect and relay interaction between the major extracellular matrices of the cochlear partition. OHCs are designed to optimize this interaction and hence the sensitivity and frequency selectivity of the cochlea. This chapter is concerned with our understanding of the workings of the cochlea largely from the measurement of receptor potentials from individual hair cells in the cochlea. This frustrating but fruitful line of research has been carried out in remarkably few laboratories over a relatively brief period of time. Only a few of us, including Mary Ann Cheatham, Peter Dallos, Fred Nuttall, Peter Sellick, Joe Zwislocki, and our hard put-upon colleagues decided that it might be easier to measure responses directly from hair cells rather than interpret extracellular potentials from the cochlea, except when the risk of confusion was relatively low. The major hazards with intracellular recording are limitations imposed by the frequency responses of the recording systems and their nonlinearity when strongly polarized. These limitations make it difficult to obtain quantitative measurements at high frequencies and high levels of electrical polarization. Other limitations are leak conductances caused by electrode penetration. These are often emphasized by patch clampers when attacking isolated cells with electrodes filled with nonphysiological solutions and obtaining findings that differ from those obtained with sharp electrodes *in vivo* measurements. These leak conductances can sometimes have real rather than imaginary consequences to the interpretation of the data. The findings from different laboratories using sharp electrodes to measure hair cell responses *in vivo* are remarkably consistent. Where they differ, the differences have usually been resolved. The origin and functional significance of cochlea potentials have been the subject of some outstanding reviews by Dallos P. (1992; 1996) .

3.20.2 A History of Sensory Transduction

This subject has been covered in a previous chapter, but it is worth reminding ourselves that our widely held understanding of hair cells as being excited by displacement of the hair bundle toward the tallest row or kinocilium, if one is present, is due to the combined electrophysiological measurements and electron microscopy of Löwenstein O. and Wersäll J. (1959) when working on the semicircular canals of the skate. The discovery that excitation was associated with hair cell depolarization is due to Flock A. (1965) measurements from lateral line organs of the freshwater cod *Lota*. He also revealed the exquisite asymmetry of the hair cell's electrical response and derived a hair cell-transfer function, which also offered an explanation for the double-frequency microphonic of the lateral line organ. Later, Hudspeth A. J. and Corey D. (1977) were the first to manipulate individual hair bundles and were able to relate the hair cell receptor potential to hair-bundle displacement in freestanding hair bundles, revealed by stripping away the otoconial membrane from the sensory epithelium of the isolated frog sacculus. The first measurements of receptor potentials from IHC (Russell, I. J. and Sellick, P. M., 1977) and OHC (Dallos, P. *et al*., 1982) depended very much on the earlier findings for their interpretation.

Sellick and Russell were also intrigued at this time by the nature of the hair cell receptor current. This came about as a consequence of Sellick's early research on the electrochemistry of the cochlea (Sellick, P. M. and Johnstone, B. M., 1975) and the present author's interest in the lateral line organs. As a consequence, we first worked on this problem in the lateral line organs of *Xenopus*, which swam in laboratory tap water, where the dominant cation was calcium. With help and encouragement from Keith Bosher, who had already made the definitive measurements of the ionic composition of endolymph (Bosher, S. K. and Warren, R. L., 1978), which bathes the hair bundles of cochlear hair cells, we discovered that the gelatinous cupula (equivalent to the TM) of lateral line organs can sustain a Donnan equilibrium and a micro, compartmentalized, environment of high levels of potassium and a positive endocupular

potential of several tens of millivolts (Russell, I. J. and Sellick, P. M., 1976). The environment bathing the apical surfaces of lateral line hair cells was, thus, remarkably similar to that bathing the apical surfaces of cochlear hair cells. From this we concluded, according to the Davis H. (1965) theory, that the dominant ion carrying the receptor current must be potassium. Olav Sand felt that we had missed a trick and insisted that we measure the free calcium concentration in the cupula. He was led to this suggestion by his frustration and finding that the tap water of Los Angeles was so contaminated with heavy metals, other than calcium, that salamander lateral line organs did not transduce if the salamanders were maintained in it (Sand, O., 1985). However, transduction was restored in the presence of calcium. He also pointed out that the calcium concentration of the endolymph measured by Bosher S. K. and Warren R. L. (1978) was very small (30 μM). Even so, 30 μM calcium is several orders larger than that which might be expected due to passive distribution of calcium in the endolymph, and therefore must be actively pumped and essential for sensory processing in the cochlea. We found similar calcium levels in the lateral line cupulae of *Xenopus*, although here we found no evidence of active pumping, but the high levels (10–30 μM) were due to diffusion from the surrounding tap water (McGlone, F. P. *et al.*, 1979). Thus Sand was the first to show that calcium was an essential element in hair cell mechanotransduction. These studies, and those of Krönester-Frei A. (1979) (see also Freeman, D. M. *et al.*, 2003a; 2003b) on the susceptibility of the TM to manipulations of the ionic composition of artificial endolymph, kept us aware that a drop in the endocochlear potential had many more implications for sensory transduction in the cochlea than a change in the driving voltage to the hair cell transducer. Our current understanding of endolymph and the production of the endocochlear potential has been the subject of several reviews in the early 2000s (e.g., Wangemann, P., 2002).

3.20.3 Compound Potentials Recorded from the Cochlea

Three important extracellular receptor potentials can be recorded, usually via an electrode placed on, or close to the round window (RW) membrane. These are the cochlear microphonic (CM), the summating potential (SP), and the compound action potential (CAP). They have been the subjects of seminal original papers and excellent reviews, including Dallos P. (1973). Experiments involving selective destruction of hair cells (Dallos, P. *et al.*, 1972) and later measurements from single hair cells (Russell, I. J. and Sellick, P. M., 1977; Dallos, P. *et al.*, 1982) provided the basis for a fuller understanding of the origin and nature of extracellular receptor potentials and their utility in studying the cellular mechanism of sensory transduction in the cochlea. Largely on the basis of these experiments, it was confirmed that the CM is a farfield potential produced almost exclusively from OHC cell-receptor currents (Dallos, P. *et al.*, 1972; 1982; Russell, I. J. and Sellick, P. M., 1983) and the CM recorded from the RW membrane is dominated by the responses of OHCs in the basal turn of the cochlea (Patuzzi, R. B. *et al* 1989; Zheng, X.-Y. *et al.*, 1997; Durrant, J. D. *et al.*, 1998; Legan, P. K. *et al.*, 2000). The SP is a DC component of the electrical response of the cochlea which, when recorded from the RW membrane, is dominated by the responses of basal turn hair cells. Experiments directed at the selective destruction of IHCs (Zheng, X.-Y. *et al.*, 1997; Durrant, J. D. *et al.*, 1998) appear to have resolved a long-standing issue on the origin of the SP concerning its generation, as least in the basal turn and for low-to-moderate stimulus levels, by attributing it largely to the IHCs when DC components of OHC responses are immeasurably small (Russell, I. J. and Sellick, P. M., 1978; Cody, A. R. and Russell, I. J., 1987; Russell, I. J. and Kössl, M., 1992a). It remains to be seen if this is the case in other turns of the cochlea. Controversy over the origin of the SP began when as a result of hair-cell lesion studies with streptomycin Davis H. *et al.* (1958a) concluded that the IHCs are the dominant source of the SP. By contrast Dallos P. (1973) proposed the OHCs as the primary source of the SP based on unpublished work with Bredberg in which they destroyed hair cells in the guinea-pig with kanamycin. Further support for an OHC origin for the SP was provided by Dallos P. and Cheatham M. A. (1976) who found SP recorded from the apical turn of the cochlea to be essentially unchanged with complete destruction of IHCs by kanamycin. In the light of later intracellular studies by Dallos P. and Cheatham M. A. (Dallos, P., 1986; Dallos, P. and Cheatham, M. A., 1991) which reveal that OHCs in the apical three turns of the guinea-pig cochlea can generate substantial DC potentials, the 3:1 outnumbering of IHCs by OHCs and that IHC receptor potentials are swamped by OHC responses when recording within the organ of Corti (Russell, I. J.

and Sellick, P. M., 1983; Cody, A. R. and Mountain, D. C., 1989), Dallos' conclusions that OHCs are the dominant source of SP, at least in the low-frequency turns of the cochlea, would appear to be justified.

The CAP is perhaps the easiest of the extracellular potentials to measure, through an electrode placed on the RW, and it is certainly the most useful. The RW electrode can record compound-action potentials from afferent fibers that innervate the entire extent of the cochlea. The same electrode will also record CM and SP, but these potentials are dominated by the responses of basal turn hair cells (Patuzzi, R. B. *et al.*, 1989). Accordingly the threshold responses of the CAP are an excellent indicator of sensitivity over the entire frequency range of the cochlea and can be used as a basis for comparison to determine the cochlear origin of sensory neural hearing loss (see Dallos, P., 1973). Simultaneous and forward-masking of the CAP can be used to produce tuning curves that are very similar in characteristics to those of single unit neural-tuning curves (Dallos, P. and Cheatham, M. A., 1976). Thus, through the relatively simple procedure of placing an electrode on the RW, one can measure the sensitivity and frequency response of the cochlea from the responses of the CAP.

3.20.4 Davis' Theory of Sensory Transduction

The significance of the remarkable ionic composition of endolymph, so similar to that of cytosol, and the associated positive endocochlear potential that usually exceeds +80 mV in most species, was first appreciated by Hallowell Davis in a model of cochlea function (Davis, H., 1965) (Figure 2(a)). According to this theory, the positive endocochlear potential in series with the hair cell resting-membrane potential provides the electromotive force for the flow of current through the gated transducer channels. At the

	K^+	Na^+	Ca^{2+}
Endolymph	150	1	0
Perilymph	5	140	2

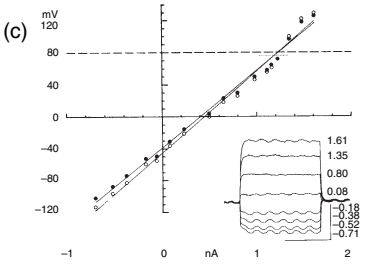

Figure 2 Davis' model of sensory transduction in the cochlea. (a) Current, largely carried by K^+ is driven by two batteries in series: the endocochlear potential (EP, +80 mV) and the cell-resting potential (−45 or −70 mV). K^+ is driven down the electrical gradient into the cell and down the chemical gradient out of the cell into the perilymph. Hair cells, therefore, expend little metabolic energy in restoring their ionic equilibrium or fatigue when transducing mechanical into electrical signals. (b) The ionic composition of the perilymph in the scala vestibuli and tympani and the endolymph of the scala media. (c) Evidence supporting Davis' theory: Reversal of the IHC receptor potential at close to the EP (+80 mV) by intracellular injection of positive current. From Russell, I. J. 1983. Origin of receptor potential in inner hair cells of the mammalian cochlea – evidence for Davis' theory. Nature 301, 334–336.

time when the model was conceived, the channels were visualized as variable resistors rather than elements with at least two states whose probability of opening was determined by hair bundle position (Kros, C. J., 1996). The current is carried by potassium, the dominant cation of the endolymph (Figure 2(b)), which is driven through the open transducer channel by the combined electromotive forces of the endocochlear potential and hair cell resting potential. The intracellular ionic composition is maintained within the hair cell by the diffusion of potassium down its concentration gradient through potassium conductances in the basolateral membrane into the surrounding perilymph.

Davis's theory was strongly supported by Sewell W. F. (1984) who found a direct association between the endocochlear potential and spontaneous discharge rates in auditory nerve fibers in that they both decreased synchronously following intravenous injections of the diuretic furosemide in anesthetized cats. He deduced that the injection of furosemide causes a decrease in the endocochlear potential, which produces a linearly related hyperpolarization of the IHC membrane potential by altering the standing current which flows through the transducer membrane. The logarithm of the rate of release of transmitter quanta decreases with the hyperpolarization of the IHC membrane potential, which decreases the rate of occurrence of action potentials at the postsynaptic terminal. The CM, SP, and CAP can all be altered through the polarization of the cochlea partition (e.g., Fernandez, C. *et al.*, 1950; Davis, H. *et al.*, 1958b). However, it was not until the experiments of Honrubia V. and Ward P. H. (1969) that polarization of the cochlear partition produced convincing evidence in support of Davis' theory. They discovered that the polarity of the CM and SP reversed at similar potentials and found a linear relationship between the magnitude and sign of these potentials and the magnitude and sign of the polarizing current in measurements from the cochleae of anoxic guinea-pigs. They were unable to reverse cochlear receptor potentials in the normal cochleae because they found it impossible to deliver sufficient current without polarizing the electrodes and short-circuiting the cochlear partition. Honrubia and Ward concluded that the results of their experiments supported Davis' theory, emphasized the role of the EP in the generation of the CM and SP, that the generation of SP and CM were related, and the major source of nonlinearity in the cochlea was the hair cell transducer. The same, but independently derived, conclusion was drawn by Santos-Sacchi J. (1993) more than two decades later. Further direct support for Davis' theory through a highly frustrating series of experiments was to inject positive current through an intracellular electrode inserted into a hair cell until the receptor potential reversed in sign (Russell, I. J., 1983; Russell, I. J. and Kössl, M., 1991). According to Davis' theory, the reversal potential should coincide with the EP. When current was injected into IHCs, the receptor potential reversed at the EP (Figure 2(c)). The frustration was caused by the electrodes, which usually had nonlinear electrical properties and had to be discarded, and the nonlinear electrical characteristics of the IHC membranes, which rectified and usually prevented depolarization to the EP. Thus support for Davis' theory came from IHCs where the transducer channels, but perhaps not the basolateral conductances, were functioning optimally.

3.20.5 IHC Receptor Potentials

IHCs are the true sensory receptors of the cochlea and respond to vibrations of the BM after they have been transformed through interactions between the OHCs, reticular laminar, TM, and the fluid of the subtectorial space. In contrast to the hair bundles of OHCs, which are firmly attached to the TM, the hair bundles of IHCs are freestanding (Lim, D. J., 1986) (Figure 1(a)). At low frequencies, IHC receptor potentials are proportional to the velocity of the BM and respond to the resultant interaction between the reticular laminar and the TM and fluid movement between them (Dallos, P. *et al.*, 1972; Sellick, P. M. and Russell, I. J., 1980; Patuzzi, R. and Yates, G., 1987; Cheatham, M. A. and Dallos, P., 1998) (Figure 1(b)). Thus IHC hair bundles are not sensitive to static displacements between the TM and reticular laminar, unless of course these static displacements influence the dynamic relationship between them. The precise way in which IHCs are excited is not understood. The mode of excitation has been inferred from the *in vivo* measurements described earlier and more recently from *in vivo* recordings from mice where the structure and relationship of the TM has been genetically modified. In these experiments it was deduced that the main drive to the fluid-coupled hair bundles of the IHCs in these mice was via radial motion of the RL at frequencies above and below the CF of the IHC and that radial

motion of the TM was required for driving the IHC hair bundles at the CF. IHC hair bundle can be directly observed in isolated preparations of the cochlea and organ of Corti (Dallos, P., 2003; Chan, D. K. and Hudspeth, A. J., 2005; Fridberger, A. *et al.*, 2006; Nowotny, M. and Gummer, A. W., 2006; Jia, S. *et al.*, 2007). This approach has the advantage of describing what can be seen, rather than inferring what is happening to the IHC hair bundles from electrical recordings and mechanical recordings from the cochlea. The disadvantage is that the slightest changes in the electrochemistry of the cochlea can have profound effects on the responses of IHCs and the properties of the TM, even at frequencies well below the CF (Russell, I. J. and Cowley, E. M., 1983; Russell, I. J. and Ashmore, J. F. 1983; Freeman, D. M., *et al.*, 2003a). Important factors in ensuring consistency between measurements made *in vivo* and *in vitro* are the calcium concentration of the ionic fluid bathing the hair bundles (see further) and the development stage of the preparation. In this respect the transducer conductance measured from mature IHCs in an isolated preparation (~30 nS, Jia, S. *et al.*, 2007) far exceeds that recorded from neonatal hair cells (~4 nS, Kros, C. J. *et al.*, 1992).

3.20.5.1 Factors That Shape the Inner Hair Cell Receptor Potential

IHCs respond to the acoustically evoked mechanical vibrations of the cochlear partition and relay these responses through synaptic transmission to the fibers of the cochlea nerve. They must perform this task over the entire frequency and dynamic ranges of the cochlea. The secret to coping with this task is encompassed within the nonlinear properties of IHC receptor potential and its operating point.

IH-receptor potentials are the products of the transducer function, which relates the hair bundle displacement to the open (or closed) probability of the mechanosensitive transducer channel (Kros, C. J. *et al.*, 1992) and the basolateral conductances and their voltage dependency (Kros, C. J., 1996; Housley, G. D. *et al.*, 2006) (Figure 3). The operating point of the hair cell transducer function is sensitive to extracellular calcium. The operating point of IHCs measured from cultures of neonatal mouse cochlea bathed in artificial perilymph with 1.4 mM Ca^{2+} is set so there is a probability of only 2–3% of the channels being open at rest. *In vivo* (Russell, I. J. and Sellick, P. M., 1978; 1983; Dallos, P., 1985), or *in vitro* (Jia, S. *et al.*, 2007) with 50 µm Ca^{2+}, the

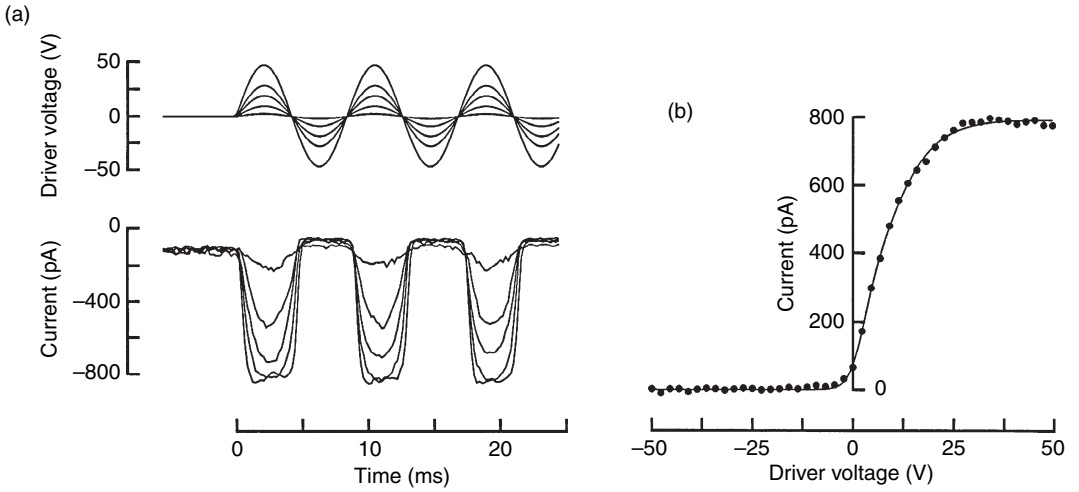

Figure 3 Transfer function of the transducer current. (a) Transducer currents of an OHC from the apical coil. Transducer currents (single traces) in response to five different driver voltages (records shown above). Responses to only the first three cycles of the sinusoid (119 Hz) are shown, to better appreciate the waveform of the responses. The currents can be seen to saturate for the largest driver voltages. The widening of the responses with increasing stimulus intensity indicates that the saturation occurs in the hair cell and not in the mechanical stimulus. Series resistance, 4.0 MΩ. (b) Transfer function of the cell of (a). Zero current is taken as the holding current when the force stimulus closes the transducer channels. Note that the currents have been inverted in this figure; inward current is plotted upwards. The maximum transducer current is 794 pA. When no force is exerted on the bundle, 66 pA of transducer current is flowing. From figure 3 of Kros, C. J., Rüsch, A., Richardson, G. P. 1992. Mechano-electrical transducer currents in hair cells of the cultured neonatal mouse cochlea. Proc. Roy. Soc. Lond. B 249, 185–193.

probability is 12–15% (Russell, I. J. and Sellick, P. M., 1978; 1983). The operating point is close to the point of maximum inflexion of the transducer function (Russell, I. J. and Kössl, M., 1992a), thereby causing the IHCs to generate a very asymmetrical receptor potential (Figures 4(a) and 4(b)).

3.20.5.1.1 Intracellular calcium levels

Intracellular calcium levels in the stereocilia in the vicinity of the mechanotransducer channel is one of the factors that determine the probability of these channels being open in their resting state (Ricci, A. J. and Fettiplace, R., 1997). These intracellular levels are also determined largely by the low extracellular levels of calcium rather than by calcium buffering in the hair bundle, which is believed to be weak. On the basis of calibrated immunogold labeling, four main calcium-buffering proteins (calbindin-D28k, calretinin, parvalbumin-α, and parvalbumin-β) are largely excluded from the hair bundles of mature rat cochlear hair cells (Hackney, C. M. *et al.*, 2005). The effect of high intracellular calcium levels is to cause adaptation by reducing the probability of the transducer channels being open at rest and to move the transducer function toward the right along the displacement axis (Kennedy, H. J. *et al.*, 2003; 2005). Thus the level of intracellular calcium determines the operating point of the transducer function. In turtle cochlear hair cells, the transducer function becomes almost symmetrical when the intracellular concentration of calcium in the hair bundles is very low, and thus the probability of mechanoelectrical channels being open in the resting state approaches 50% (Fettiplace, R. and Ricci, A. J., 2003; Fettiplace, R., 2006; Le Masurier, M. and Gillespie, P. G., 2005; Gillespie, P. G. and Cyr, J. L., 2004).

3.20.5.1.2 Voltage-dependent basolateral conductances

Another major influence that shapes the receptor potential-displacement function is the voltage-

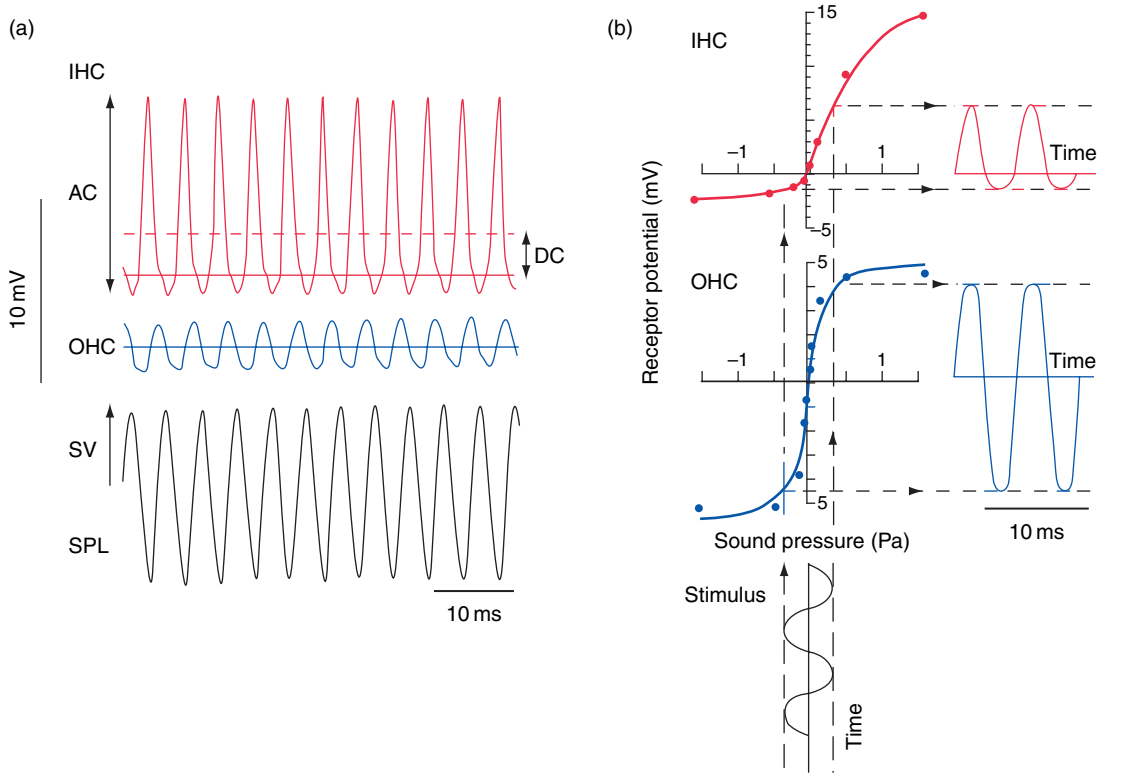

Figure 4 The operating characteristics of their transducer functions are related to the different roles of IHC and OHCs. (a, b) IHCs (red traces) operate about an asymmetrical point on their input–output curve. Thus they can generate DC voltage responses to high-frequency tones and hence signal their responses to the postsynaptic afferent fibers. OHCs (blue traces) operate about the steep, most sensitive region of their input–output curve. OHCs feed back energy to the cochlear partition, thereby boosting the swing of the BM to overcome viscous damping.

dependent basolateral conductances (Kros, C. J. and Crawford, A. C., 1990; Kros, C. J., 1996; Housley, G. D. *et al.*, 2006). These conductances are summarized in Figure 5. Recent models have taken into account the mechanotransducer channel as a mechanically driven potassium conductance and two time- and voltage-dependent basolateral potassium conductances: one with fast and one with slow kinetics (van Emst, M. G. *et al.*, 1997; Zeddies, D. G. and Siegel, J. H., 2004; Lopez-Poveda, E. A. and Eustaquio-Martín, A., 2006). The model developed by van Emst *et al.* was used to assess the contribution of basolateral potassium currents to the summating potential. Zeddies and Siegel used their model to investigate the homeostatic mechanisms responsible for the resting potential of the IHC, while Lopez-Poveda and Eustaquio-Martín developed a model to assess the contribution of basolateral potassium currents to the IHC nonlinear input/output transfer characteristics measured *in vitro* or *in vivo*. In the van Emst *et al.* model without the potassium conductances, the receptor potentials are determined by the properties of the transducer function and they are very asymmetrical with a correspondingly large DC component. The effect of switching on both the fast and slow potassium conductance as a consequence of the depolarization due to the activation of the transducer conductance is to decrease the overall amplitude of the receptor potential. This leads to a marked decrease in the DC component of the receptor potential as a consequence of a shift in the operating point to a more symmetrical location. Thus the nonlinearity of the receptor potential and its operating point, both so crucial for the generation of voltage responses to tones and their transmission to the afferent nerve fibers, are potentially vulnerable to voltage- and ion-dependent modification. Transient asphyxia causes profound modifications to the ionic and electrical environment of hair cells. It is possible, therefore, that the reduced nonlinearity and increased symmetry of their operating characteristics, and hence increased symmetry of the receptor potentials and decrease in the DC component recorded from asphyxic animals, are a consequence of changes in the electrochemistry of the cochlea (Russell, I. J. and Cowley, E. M., 1983; Russell, I. J. and Ashmore, J. F., 1983).

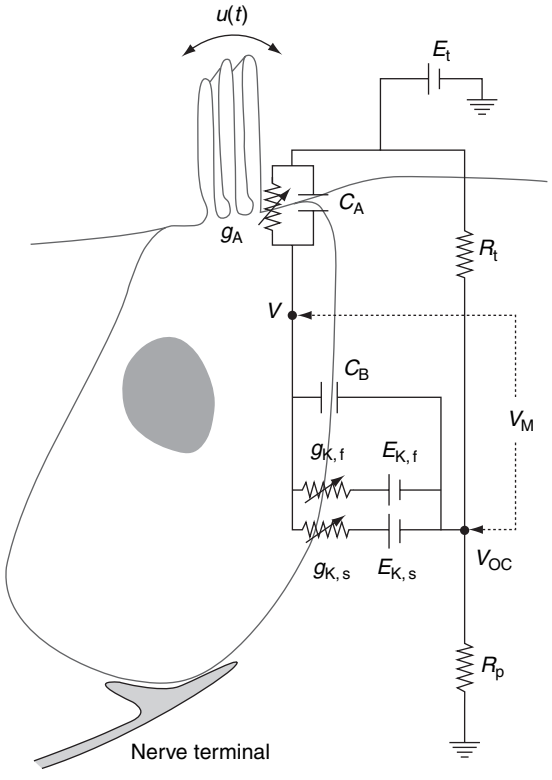

Figure 5 Model diagram: electrical equivalent circuit of the cell. E_t = endocochlear potential; R_t, R_p = epithelium resistances. C_A, C_B = capacitance of the apical and basal portions of the cell's membrane, respectively. g_A = conductance of the apical portion of the cell's membrane; it is assumed to be the sum of a mechanically sensitive K^+ conductance, $g_m(u)$, and a leakage conductance, g_l (not shown). $g_{K,f}$, and $g_{K,s}$ = fast and slow basolateral K^+ conductances. $E_{K,f}$ and $E_{K,s}$ = reversal potentials of the fast and slow basolateral K^+ conductances, u = stereocilia displacement, V = IHC intracellular potential. V_{OC} = extracellular potential. V_M = membrane potential, defined as $V - V_{OC}$. From figure 1 of Lopez-Poveda, E. A. and Eustaquio-Martin, A. 2006. A biophysical model of the inner hair cell: The contribution of potassium currents to peripheral auditory compression. J. Assoc. Res. Otolaryngol. 7, 218–235.

3.20.5.1.3 Inner Hair Cell receptor potential transfer function and operating point depend on cochlear location

IHC receptor potentials vary in shape and operating point depending on whether they are recorded from apical or basal turns of the cochlea. These differences are illustrated in Figure 6 and reveal that the receptor potentials of apical IHCs operate about a more symmetrical operating point and do not saturate so strongly in the negative direction compared to IHC receptor potentials from the basal region. Differences in operating point between apical and basal hair cells were not detected in whole cell measurements from IHCs in a hemicochlea preparation where the IHCs were excited through BM displacement and the apical surfaces were perfused with artificial endolymph

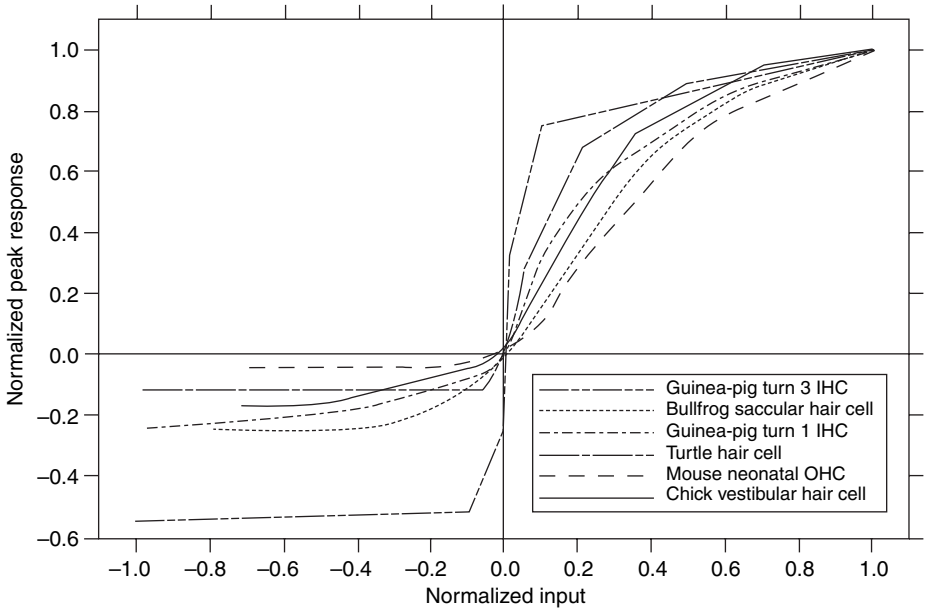

Figure 6 Sensory transducers in a variety of hair cell preparations. Transducer functions are plotted on normalized axes to facilitate comparisons *in vivo* from guinea-pig turn 3 (Cheatham, M. A. and Dallos, P. 1999) and turn 1 (Russell, I. J. and Sellick, P. M. 1983), and *in situ* from the turtle cochlea (Crawford, A. C. and Fettiplace, R. 1981). The *in vitro* data represent vestibular hair cells from bullfrog (Hudspeth, A. J. and Corey, D. P. 1977) and chick (Ohmori, H., 1987), as well as cochlear OHCs from a neonatal organ culture in the mouse (Kros, C. J. *et al.*, 1992). Only the chick and mouse results, however, provide true transducer functions. In all other preparations the receptor potential, rather than the receptor current, was measured. From figure 9 of Cheatham, M. A. and Dallos, P. 2000. The dynamic range of inner hair cell and organ of Corti responses. J. Acoust. Soc. Am. 107, 1508–1520.

(Jia, S. *et al.*, 2007). The slopes of the relationship between BM displacement and the mechanoelectrical transducer current were found, however, to be twice as steep for basal IHCs than for apical IHCs, although in contrast to OHCs (He, D. Z. Z. *et al.*, 2004), the total transducer conductances of apical and basal IHCs are similar. The finding that the BM displacement required in the apex to produce a given level of IHC (and OHC, He, D. Z. Z. *et al.*, 2004) excitation are about twice those needed to excite IHCs in the base of the cochlea, is due to a consequence of geometry. A given BM displacement in the base produces a larger hair bundle displacement (Dallos, P., 2003). It is hard to estimate IHC hair bundle displacement, however, because the stereocilia are not directly attached to the TM and their angular rotation due to TM displacement is frequency-dependent and difficult to deduce. The bases for regional differences in the shape of the IHC receptor potential recorded *in vivo* are not known. Possible candidates are regional differences in the intracellular levels of calcium in the vicinity of the transducer conductances and regional differences in the contributions of the voltage-dependent conductances. With respect to the latter possibility, the greatest density of voltage-dependent conductances is apparently found in hair cells in the base of the cochlea (Housley, G. D. and Ashmore, J. F., 1992; Mammano, F. *et al.*, 1995) and expression of KCNQ4 channels, which are represented by M-type conductances and are the linopiridine-sensitive $I_{K,n}$ present in IHCs and OHCs (Kros, C. J. *et al.*, 1998; Marcotti, W. and Kros, C. J., 1999; Marcotti, W. *et al.*, 2003; Oliver, D. *et al.*, 2003; Wong, W. H. *et al.*, 2004), are greatest in the IHCs and spiral ganglion neurones of the basal, high-frequency region of the cochlea (Beisel, K. W. *et al.*, 2000; 2005; Fritzsch, B. and Beisel, K. W., 2003). The functional significance of this distribution is, however, not fully appreciated at present, although mutations of the KCNQ4 channels known as *DFNA2* cause nonsyndromic, autosomal-dominant, progressive high-frequency hearing loss, whose cellular and molecular basis is unclear (Beisel, K. W. *et al.*, 2005).

Interestingly, the responses of IHCs to negative current injection depend on whether the IHCs are

from the apical or basal regions of the cochlea. One might anticipate that negative current injection, which hyperpolarizes the membrane, would tend to increase the driving voltage for calcium through the transducer conductance, thereby increasing the level of intracellular calcium in the hair bundle. Increased levels of intracellular calcium decrease the probability of the transducer conductance being open at rest (Crawford, A. C. *et al.*, 1991; Ricci, A. J. and Fettiplace, R., 1997). This change would shift the receptor potential displacement function toward the direction of reduced sensitivity, the operating point toward the point of maximum inflexion, and the DC component relative to the AC component would increase. Similar effects would also be produced as a consequence of inactivating the fast and slow potassium currents as a consequence of negative current injection, as predicted by van Emst M. G. *et al.* (1997). Indeed these predicted effects are observed when the apical turn IHCs are hyperpolarized (Cheatham, M. A. and Dallos, P., 2000) (Figure 7(a)). They are not seen, however, in the responses of basal turn IHCs, which become more symmetrical with a reduction in the saturation of the inhibitory phase of the receptor potential (Russell, I. J. and Kössl, M., 1991) (Figure 7(b)). The basis of this apical-basal difference in IHC response to current injection is unknown. Perhaps it is linked to an apex-to-base increase in the concentration of KCNQ4 channels (Beisel, K. W. *et al.*, 2005). Oliver D. *et al.* (2003) propose that KCNQ4 currents contribute substantially in establishing the resting membrane potential of IHCs and in so doing control low levels of intracellular $[Ca^{2+}]$. Moreover, several reports have suggested that intracellular Ca^{2+} may regulate KCNQ channels by reducing the magnitude of the current (Gamper, N. and Shapiro, M. S., 2003). The equilibrium conditions for the putative positive feedback between the conductance of KCNQ4 currents and intracellular $[Ca^{2+}]$ (Gamper, N. and Shapiro, M. S., 2003) may be finely balanced. Perhaps in basal IHCs, with a large concentration of KCN4 channels, hyperpolarization results in a stronger driving force for the influx of $[Ca^{2+}]$, but activation of the KCN4 channels results in lowering of intracellular $[Ca^{2+}]$ as a consequence of inactivating voltage-dependent conductance in the basolateral membranes (Hafidi, A. *et al.*, 2005). A reduction in intracellular calcium increases the probability of the transducer conductance being open at rest. The receptor potential displacement function will therefore shift to the left and increase the DC component of the receptor potential.

3.20.5.2 Transfer Functions of Afferent Synapses

IHCs are responsible for the translation of receptor potentials into neuronal signals with calcium playing an essential role in controlling the release of neurotransmitters at the IHC afferent synapse (Zhang, S. Y. *et al.*, 1999; Beutner, D. *et al.*, 2001). Sound-induced depolarizations of the IHC-membrane potential lead to the activation of $Ca_v1.3$ L-type voltage-gated channels located in the basolateral membrane (Dulon, D. *et al.*, 1995; Kros, C. J. *et al.*, 1998; Platzer, J. *et al.*, 2000; Brandt, A. *et al.*, 2003; Langer, P. *et al.*, 2003; Skinner, L. *et al.*, 2003; Hafidi, A. and Dulon, D., 2004; Marcotti, W. *et al.*, 2004). L-type calcium channels are believed to be primarily responsible for controlling both spontaneous and sound-evoked transmitter release from IHCs (Robertson, D. and Paki, B., 2002; Sueta, T *et al.*, 2004). Calcium entry leads to the fusion of vesicles and release of glutamate from the presynaptic membrane to bind with receptors on the afferent synaptic bouton (Glowatzki, E. and Fuchs, P. A., 2002).

The ribbon synapses of hair cells (Figure 8) release transmitter spontaneously and in a graded way in response to varying stimulus amplitudes over a wide frequency range (Raphael, Y. and Altschuler, R. A., 2003; Fuchs, P. A. *et al*, 2003; Fuchs, P. A., 2005). There are relatively few examples of *in vivo* intracellular recordings from the afferent terminals of hair cells. Furukawa and his colleagues (e.g., Furukawa, T. and Ishii, Y., 1967; Ishii, Y. *et al.*, 1971; Furukawa, T. and Matsuura, S., 1978; Furukawa, T. *et al*, 1978) made the first recordings from the giant afferent fibers of the goldfish sacculus, Flock A. and Russell I. J. (1973; 1976) recorded presynaptic and postsynaptic responses from hair cells and their afferent innervation from lateral line receptors in the freshwater cod *Lota*. Siegel J. H. and Dallos P. (1986) and Siegel J. H. (1992) recorded postsynaptic spikes and excitatory postsynaptic potentials (EPSPs) from afferent fibers close to IHCs (Figure 9(a)). Russell I. J. and Sellick P. M. (unpublished) and Palmer A. R. and Russell I. J. (1986) recorded IHC receptor potentials and postsynaptic potentials from an immediately adjacent afferent terminal, but did not record action potentials (Figure 9(b)). The vast majority of measurements have been from hair cell and isolated preparations of one form or another, with the advantages that

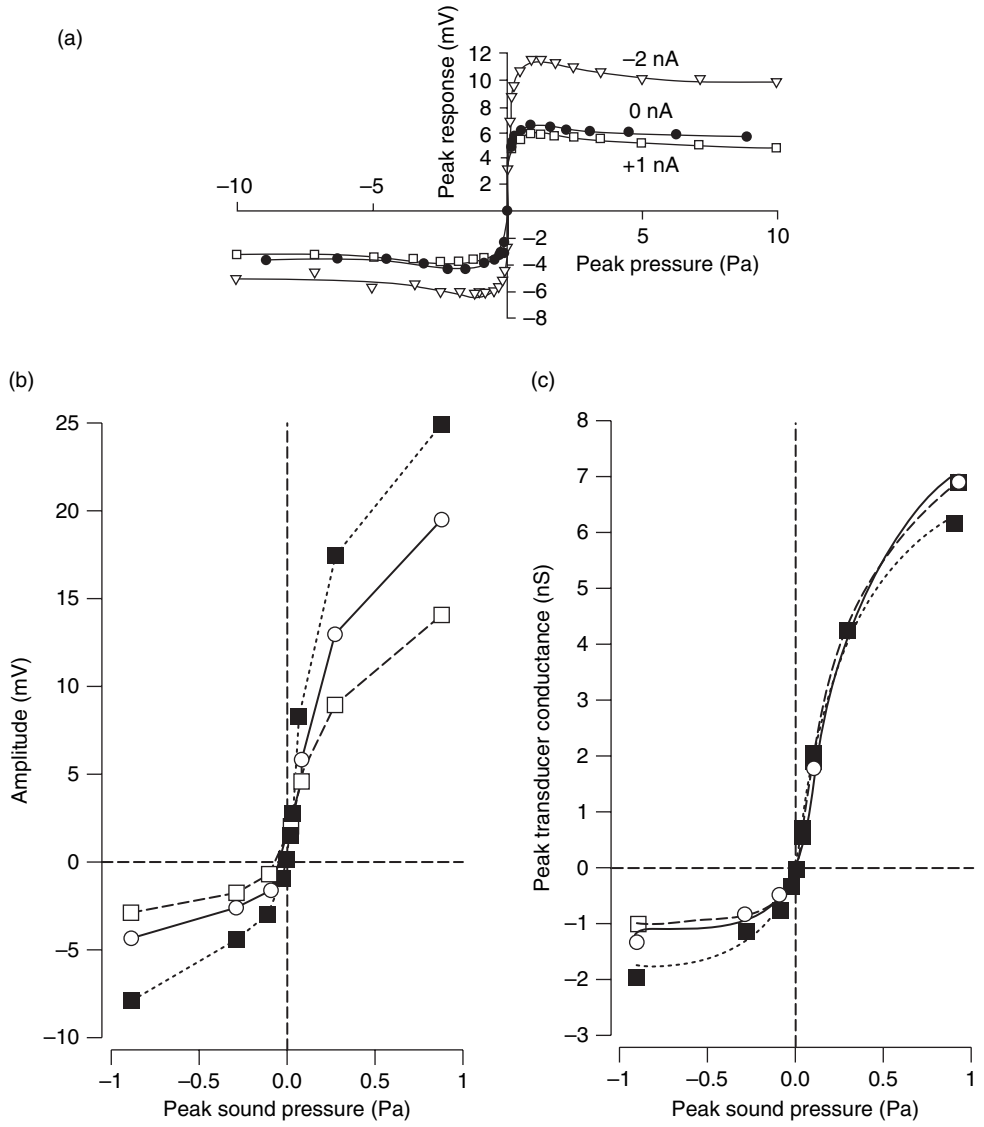

Figure 7 IHC transducer functions during current injection. (a) Input–output functions for the fundamental AC response recorded from a third-turn IHC plotted as linear response magnitude (depolarizing and hyperpolarizing peaks of the response) versus linear peak pressure from averaged waveforms. Data were obtained from Fourier transforms of the averaged responses to tone bursts. Stimulus frequency is 700 Hz. Data are shown for three current levels, 0, −2, and +1 nA passed into the cell through the recording electrode. Positive peaks are arbitrarily assigned to positive pressure. (b) Relationship between peak sound pressure and the peak negative and peak positive receptor potentials of an IHC. Zero current injection (○, continuous line); +1.2 nA (■, dashed line) current injection; −1.2 nA (□, dotted line) current injection. Stimulating frequency 300 Hz. (c) Peak transducer conductance estimates for the receptor potentials shown in (a) as functions of peak sound pressure and compensated for the IHC membrane time constant. The lines and symbols have the same meaning as in (a) and the curves are composed of two hyperbolic tangent functions. (a) From figure 3 of Dallos, P. and Cheatham, M. A. 1990. Effects of electrical polarization on inner hair cell receptor potentials. J. Acoust. Soc. Am. 87, 1636–1647. (b, c) From figure 4 of Russell, I. J.and Kössl M. 1991. The voltage responses of hair-cells in the basal turn of the guinea-pig cochlea. J. Physiol. Lond. 435, 493–511.

afferent transmission is more accessible for study but with various limitations imposed by the conditions of the experimental investigation. In the early 2000s, Glowatzky E. and Fuchs P. A. (2002) performed a major technological feat when they made whole-cell patch recordings from the postsynaptic terminals of single IHC afferent fibers in a cochlea slice preparation (Figure 10).

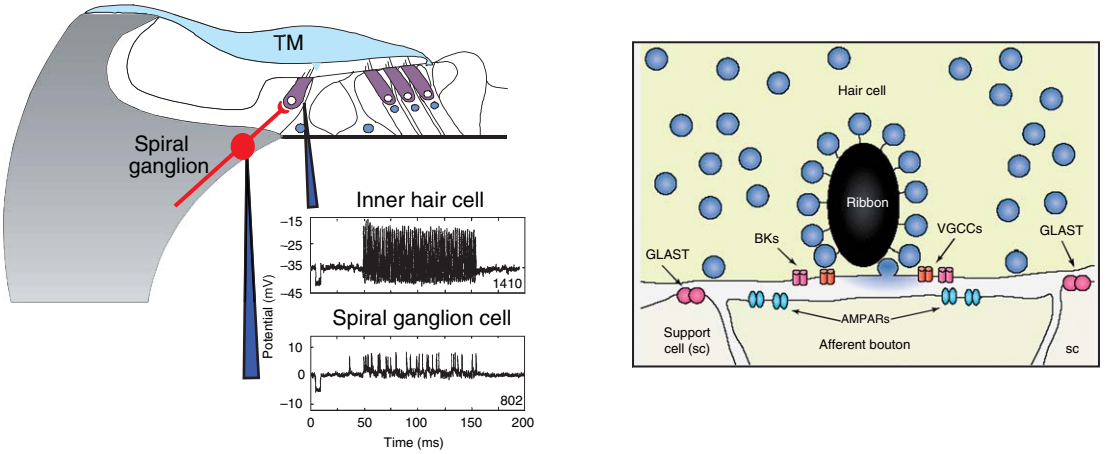

Figure 8 The hair cell's ribbon synapse. (a) Receptor potentials modulate transmitter release from the ribbon synapses at the basal membrane of the IHC and modulate the firing pattern of afferent neurons in the spiral ganglion. (b) The IHCs afferent synapse is demarcated by an electron-dense synaptic body, or ribbon, to which small, clear-core synaptic vesicles are tethered. In the mammalian cochlea the ribbon is around 0.2 μm in diameter, and the synaptic vesicles are 35–40 nm. Voltage-gated calcium channels (VGCCs) and BK-type (calcium-sensitive) voltage-gated potassium channels are clustered near the synaptic ribbons. AMPA receptors are found on the postsynaptic afferent bouton; glutamate transporters (GLAST) are expressed by supporting cells that surround the IHC and its afferent contacts. Figure 10 Excitatory postsynaptic currents (EPSCs) recorded from IHC afferent synapses *in vitro*. (a) Two afferent boutons visualized at the base of an IHC, one with attached pipette tip for whole-cell recording. (Right) EPSCs in afferent fibers of IHCs. Whole-cell recordings; holding potential (V_h) −94 mV. (b) Monophasic EPSCs with fast rise times and a slower exponential decay in 40 mM K^+, aligned at rise time. These represent about 70% of EPSCs in all recordings. Inset shows double EPSCs observed occasionally. (c) Multiphasic EPSCs with a wide range of waveforms, many consisting of a number of events dispersed in time. These represent about 30% of EPSCs in each recording From figure 2 of Glowatzki, E. and Fuchs, P. A., 2002. Transmitter release at the hair cell ribbon synapse. Nat. Neurosci. 5, 147–154.

3.20.5.3 Phase Relationships between Inner Hair Cell and Neural Excitation

On the basis of intracellular recordings from IHCs, the phase difference between the time when the hair cell depolarizes, thereby inducing transmitter release and neural excitation remains a contentious issue. At low frequencies, the relationship between hair cell depolarization and position of the BM is consistent in all frequency regions of the cochlea and IHC depolarization is generally observed near maximum BM velocity toward scala vestibuli, as might be expected if the hair bundles are freestanding (Dallos, P. *et al.*, 1972; Sellick, P. M. and Russell, I. J., 1980; Dallos, P. and Santos-Sacchi, J., 1983; Patuzzi, R. and Yates, G., 1987; Cody, A. R. and Mountain, D. C., 1989, Kössl, M. and Russell, I. J., 1992; Legan, P. K. *et al.*, 2000). In whole cell recordings from IHCs in the gerbil hemicochlea, Jia S. *et al.* (2007) pointed out that adaptation effects also contribute to the phase relationship between BM displacement and receptorpotential generation. The time constant of mechanoelectrical adaptation is level-dependent and at the lowest level behaves as a high-pass filter with a pole at 455 Hz. Thus IHC responses to frequencies above ~500 Hz should be minimally influenced by the effects of adaptation. It is likely, therefore, that adaptation is not the basis for the inconsistencies between timing between IHC and neural excitation that exist between the apex and base of the cochlea. IHC and neural excitation is associated with maximum velocity toward the scala vestibuli at the apex of the cochlea, but in the base of the cochlea, neural excitation is associated with BM velocity toward scala tympani (Ruggero, R. A. *et al.*, 1996), which is ~180° out of phase with IHC excitation measured in this region. Cheatham M. A. and Dallos P. (1998) suggest that the temporal disparity between IHC and neural data from the base of the cochlea may relate to several factors that influence transmembrane voltage in IHCs. Extracellular voltages (Sellick, P. M. *et al.*, 1982; Russell, I. J. and Sellick, P. M., 1983) can potentially affect low- and high-frequency regions differently because electrical interactions are more likely in the base of the cochlea than in the apex (Dallos, P., 1983, 1985). The velocity-dependence of IHCs in the apex appears to extend to higher frequencies than the velocity-dependence demonstrated for IHCs in the base of the cochlea. Sellick P. M. and Russell I. J. (1980) and Russell I. J. and Sellick P. M. (1983) observed that IHC excitation in the base of the cochlea switched from BM velocity to displacement toward scala vestibuli above ~200 Hz, compared with 340 Hz for apical OHCs (Cheatham, M. A. and Dallos, P., 1999). Cheatham and Dallos point out an anatomical correlation for this finding in that the tallest stereocilia at the base of the cochlea are found on inner rather than outer, hair cells (Lim, D. J., 1980; Wright, A., 1984). This is significant because it is the height of the stereocilia, in combination with the width of the subtectorial space, which determines input to the IHC (Freeman, D. M. and Weiss, T. F., 1990; Legan, P. K. *et al.*, 2005). The transition region where OHC stereocilia become shorter than IHC stereocilia occurs at a place along the cochlear partition (Eldredge, D. H. *et al.*, 1981) that is similar to the place where response phase changes in the single-unit recordings (Ruggero, M. A. *et al.*, 1996). It is, therefore, possible that the difference in response

phase, for low- versus high-BF nerve fibers, relates to the wider frequency range over which the velocity dependence of the IHC transducer contributes to apical IHC responses. Cheatham M. A. and Dallos P. (1999) also refer to the increased nonlinearity of the transducer conductance of basal turn IHCs compared to apical IHCs (see earlier in the chapter), and differences in basolateral voltage-dependent conductances with location along the length of the cochlea (also see earlier) as bases for the apparent phase difference between IHC and neural excitation in the base of the cochlea. They propose that a potentially confounding technical problem in attempting to resolve this issue is the possible short-circuiting of voltage-dependent conductances by leak conductances in the IHC membrane caused by the penetration of the micropipette used to make the intracellular recordings. In a schematic model, where they take into account these various considerations, they can, in theory, match the phase of IHC and neural excitation in the base of the cochlea (Figure 11).

3.20.5.4 Control of Transmitter Release from the Inner Hair Cell Afferent Synapse by the AC and DC Receptor Potentials

The asymmetry of the operating point of the receptor potential enables IHCs to generate DC receptor potentials to tones at all frequencies and levels within the range of the cochlea. At frequencies below the electrical cut-off of the IHC membrane time constant, IHCs generate both AC and DC components of the receptor potential and thus have the potential to signal both, the envelope of the acoustic stimulus and its phasic components. The AC component will depolarize the IHC during BM displacements toward the scala vestibuli and hyperpolarize it during BM displacements toward the scala tympani. IHC synapses release synaptic transmitter continuously, even in the absence of acoustic stimulation (Palmer, A. R. and Russell, I. J., 1986; Siegel, J. H. and Dallos, P., 1986; Siegel, J. H., 1992; Fuchs, P. A. *et al.*, 2003; Fuchs, P. A., 2005). Thus for frequencies below those set by the IHC's membrane time constant (<1 kHz), determined by the membrane capacitance (8–16 pF, Russell, I. J. and Sellick, P. M., 1978; 6–13 pF, Kros, C. J. and Crawford, A. C.1990) transmitter release can be both increased and decreased, during the depolarizing and hyperpolarizing phases of the IHC receptor potential, respectively (Palmer, A. R. and Russell, I. J., 1986). For frequencies above the membrane time constant, the IHC receptor potential is dominated by the depolarizing DC component and transmitter release can only be increased from the baseline spontaneous rate. The speed of vesicle fusion and transmitter release/diffusion contribute to low-pass filtering (Rose, C. and Weiss, T. F., 1988; Kidd, R. C. and Weiss, T. F., 1990), but the IHC membrane time constant is the most important factor in determining the range over which afferent fibers can code the phasic components of the receptor potential, otherwise known as phase-locking.

3.20.5.5 Inner Hair Cell Membrane Time Constant and Phase-Locking

In response to low-frequency sinusoidal stimuli the discharges in fibers of the auditory nerve do not occur randomly in time. Action potentials are elicited by unidirectional movements of the BM (Davis, H. *et al.*, 1950; Goldstein, M. H., 1968; Brugge, J. F. *et al.*, 1969) and thus discharges occur within a well-defined time window relative to a single cycle of the sinusoid. This preferred timing of action potentials has been termed phase-locking of the discharge (Rose, J. E. *et al.*, 1967) (Figures 12(a) and 12(b)). Phase-locking occurs in auditory neurons of all vertebrate classes (see Palmer, A. R. and Russell, I. J., 1986; Köppl, C., 1997; Figure 13). Phase-locking in response to low-frequencies can be observed in all auditory nerve fibers irrespective of their best frequency. However, the ability of the whole ensemble of auditory nerve fibers to phase-lock decreases with stimulus frequency. Interestingly there are large differences between species in the frequency range over which phase-locking is observed (Figure 13). Thus in cat, squirrel monkey, blackbird, and pigeon, phase-locking is constant up to about 2 kHz and then declines so that it is no longer detectable at 5–6 kHz (Rose, J. E. *et al.*, 1967; Kiang, N., 1965; Kim, D. O. and Molnar, C. E., 1979; Johnson, D. H., 1980; Sachs, M. B. *et al.*, 1974; 1980). In the guinea-pig phase-locking begins to decline at about 600 Hz and is no longer detectable above 3.5 kHz (Palmer, A. R. and Russell, I. J., 1986). The owl appears to be exceptional since good phase-locking is observed up to 9 kHz (Sullivan, W. E. and Konishi, M., 1984; Köppl, C., 1997).

3.20.5.5.1 Inner Hair Cell membrane time constant: significance for phase-locking

In a series of measurements from the guinea-pig cochlea Palmer A. R. and Russell I. J. (1986) found

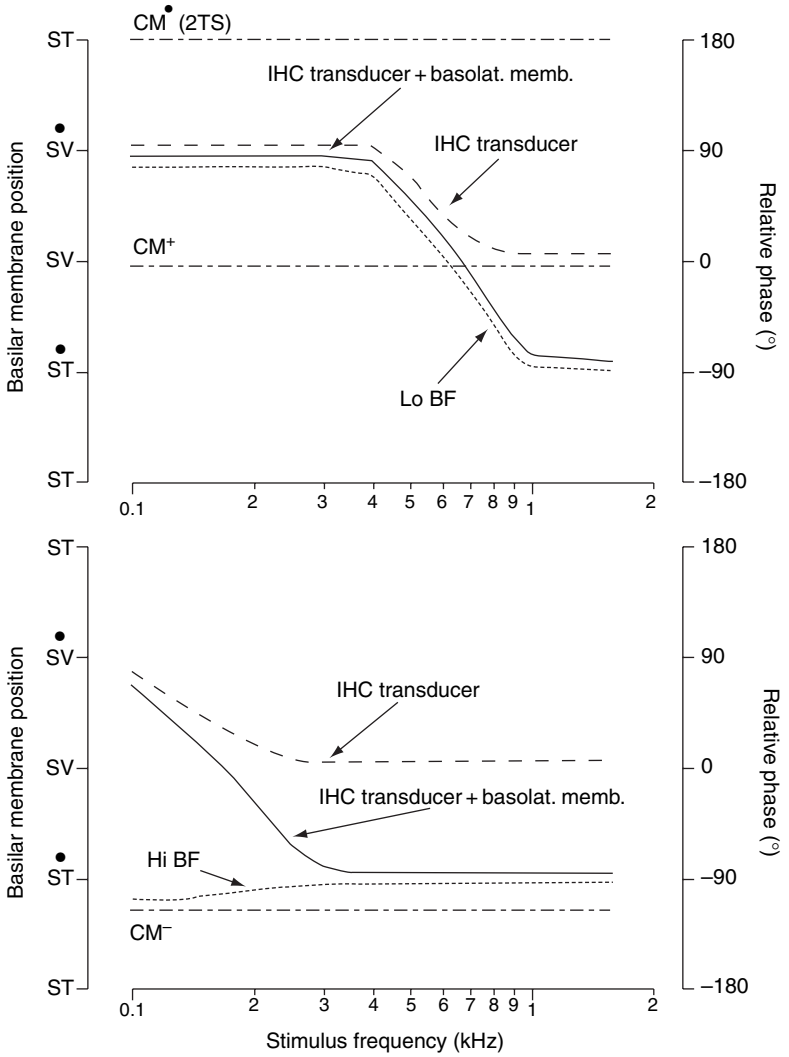

Figure 11 Resolving the phase ambiguity between IHC and neural excitation at the base of the cochlea. Summary representations of the response phase for hair cells and single-units in the apex (top panel) and base (bottom panel) of the cochlea, based on single-unit results in the chinchilla (Ruggero, M. A. *et al.*, 1996). The left ordinate represents BM position; the right, response phase plotted relative to SV displacement, with positive numbers indicating phase leads. The top panel indicates that the IHC transducer (dashed lines) responds to SV velocity at low frequencies. In other words, a 90° lead is expressed relative to the positive phase of the CM response (dot–dashed lines), which is associated with BM displacement to SV. As stimulus frequency increases, however, IHC excitation coincides with BM displacement to SV. In this case, the time of excitation is ~180° out of phase with the negative CM response. The phase of excitation for single units with low BFs (solid lines) indicates that they also respond to SV velocity at low frequencies. The IHC data reported here suggest that these neural responses should pass through SV displacement and finally settle at ST velocity as stimulus frequency increases. Above ~1000 Hz, the one fourth-cycle disparity between the single unit and the IHC transducer reflects the 90° phase lag associated with low-pass filtering by the IHC's basolateral membrane. For single units with high BFs, depicted at the bottom, a preference for ST velocity is demonstrated throughout the frequency range depicted here. The negative phase of the CM response is plotted near ST velocity to reflect nonlinearities associated with the high levels required to reach threshold for inputs well below BF. From figure 7 of Cheatham, M. A. and Dallos, P. 1999. Response phase: a view from the inner hair cell. J. Acoust. Soc. Am. 105, 799–810.

that the progressive decrease in the AC component compared to the DC component of the IHC receptor potential as the stimulus frequency was increased was closely associated with the decline in phase-locking of auditory nerve fibers (Figures 12(c) and 12(d)). Palmer and Russell concluded that the cut-off and slope of the decline in the AC component is consistent with the suggestion that this process is the limiting factor in

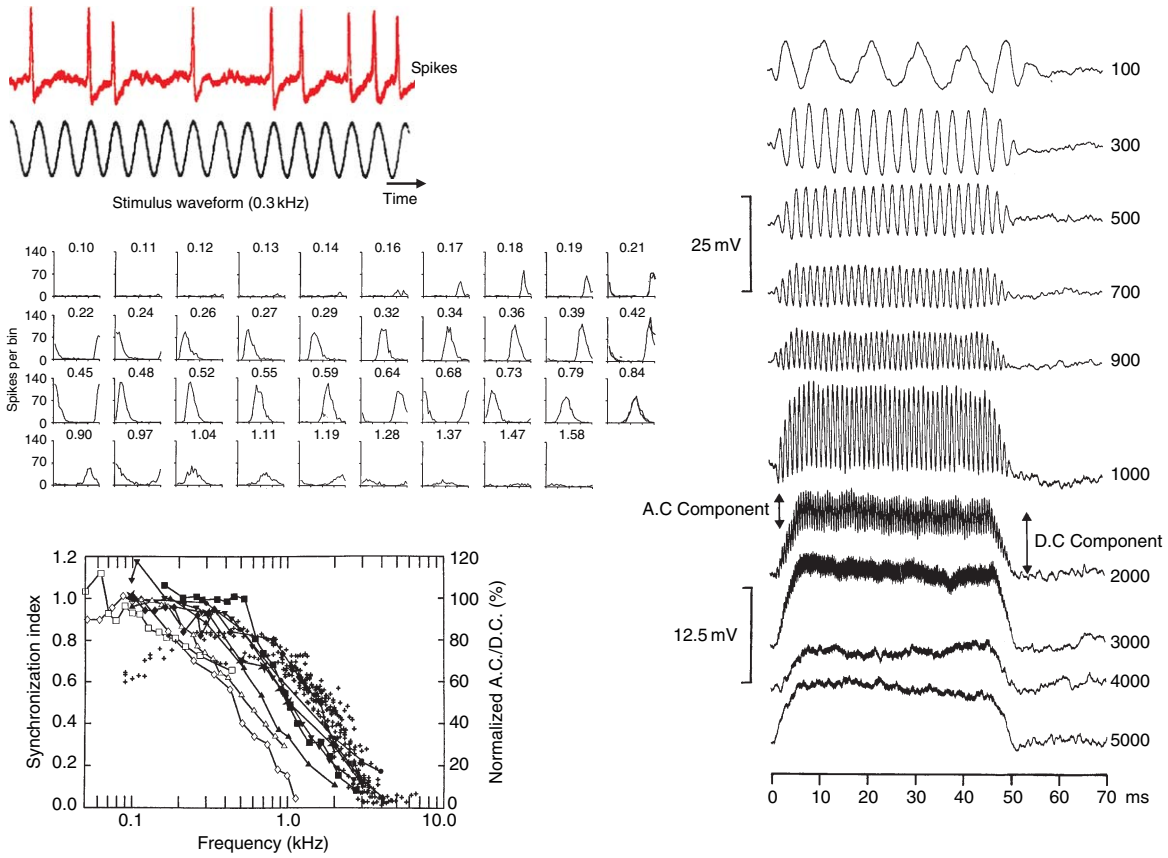

Figure 12 Comparison of the limits of phase-locking in the guinea-pig auditory nerve and the IHC membrane time constant. (a) Phase-locking of an auditory nerve spike discharge to a 300 Hz tone. (b) Period histograms of the response of a cochlear nerve fiber with a CF 0.6 kHz to sinusoidal stimulation. The numbers above the histograms indicate the stimulus frequency. The ordinate of each histogram is one cycle. (c) The membrane time constant attenuates the AC component of the IHC intracellular receptor potential recorded in the basal turn of the guinea-pig cochlea for frequencies above ~200 Hz. For frequencies below about 2 kHz, the AC component controls transmitter release, which is phase-locked to the stimulus. Above 2 kHz, the DC component predominates and controls the spike discharge rate. (d) Comparison of the limits of phase-locking in the guinea-pig auditory nerve and the ratio of the AC and DC components of the IHC receptor potential in 9 hair cells. The DC component was either calculated from the difference between the half-peak AC component and the resting potential or by the integral of the waveform. The hair cell data have been normalized by plotting as a percentage of the low frequency AC/DC ratio. (a) From Rose, J. E., Brugge, J. F., Anderson, D. J., and Hind, J. E. 1967. Phase locked response to low-frequency tones in single auditory nerve fibres of the squirrel monkey. J. Neurophysiol. 30. 769–793. (b–d) From figures 9 and 11 of Palmer, A. R. and Russell, I. J. 1986. Phase-locking in the cochlear nerve of the guinea-pig and its relation to the receptor potential of inner hair-cells. Hear. Res. 24, 1–15.

cochlear nerve fiber phase-locking. As pointed out subsequently by Rose C. and Weiss T. F. (1988), other mechanisms, probably due to time-limiting processes associated with synaptic transmission and afferent spike generation, also contribute to the high-frequency attenuation of phase-locking. For frequencies above ~3 kHz, phase-locking declines more rapidly than would be predicted from the membrane time constant of the IHC. The significance of synaptic mechanisms in providing a time-limited step in phase-locking is discussed ahead in relation to synaptic transmission.

3.20.5.5.2 The problem of preserving high temporal resolution in synaptic transmission

The superior temporal resolution of mammalian and avian auditory nerve fibers compared with those of amphibia and reptiles cannot be attributed to core temperature differences but to other differences, for example, in synaptic transmission and spike initiation in the afferent fibers (Palmer, A. R. and Russell, I. J., 1986; Rose, C. and Weiss, T. F., 1988; Köppl, C., 1997). The temporal resolution of

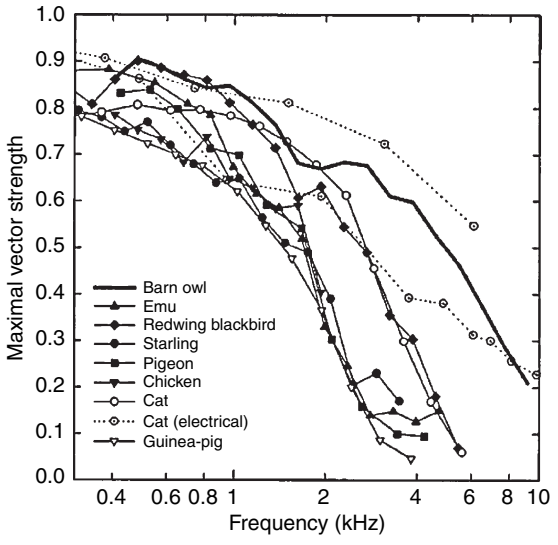

Figure 13 A comparison of maximal vector strength as a function of frequency in the auditory nerve of several avian and mammalian species. For the bird species, median values in mostly quarter octave bins are shown, taken or calculated from the following sources: barn owl, data from figure 4*A* in Köppl, C., 1997; emu, figure 9 in Manley G. A. *et al.* (1997); redwing blackbird, figure 11-9*B* in Sachs *et al.* (1980); starling, figure 4 in Gleich O. and Narins P. M. (1988); pigeon, graphic estimate of median values from figure 2 in Hill, K. G. *et al.* (1989); chicken, from figure 16 in Salvi R. J. *et al.* (1992). For the cat and guinea-pig, average values in 0.1 decade bins as determined by Weiss T. F. and Rose C. (1988, figure 3) from the original data (Johnson, D. H., 1980; Palmer, A. R. and Russell, I. J., 1986) are shown. The two different data sets for electrical stimulation in the cat (Hartmann, R. and Klinke, R. 1987; Dynes, S. B. C. and Delgutte, B., 1992) are mean values taken from figure 10 in Dynes S. B. C. and Delgutte B. (1992). From figure 11 of Köppl, C. 1997. Phase locking to high frequencies in the auditory nerve and cochlear nucleus magnocellularis of the barn owl, *Tyto alba*. J. Neurosci. 17: 3312–3321.

neural firing has also been assessed using Wiener–Kernel analysis of the responses to noise and tones by chinchilla auditory nerve fibers (Temchin, A. N. *et al.*, 2005; Recio-Spinosa, A. N. *et al.*, 2005). Temchin *et al.* and Recio-Spinosa *et al.* revealed that temporal responses are preserved in postsynaptic responses of chinchilla auditory nerves at least to 12 kHz. These events occur at frequencies beyond the limitations of the membrane time constant of the IHC. From *in vivo* recordings of afferent terminals the synaptic delay is 700–800 μs (Palmer, A. R. and Russell, I. J., 1986) (Figure 9(b)) and transmitter release is coordinated (Siegel, J. H. and Dallos, P., 1986; Siegel, J. H., 1992) (Figure 9(a)), which is in accord with more recent studies on isolated preparations (Glowatzki, E. and Fuchs, P. A., 2002; Edmonds, B. W. *et al.*, 2004; Singer, J. H. *et al.*, 2004; Khimich, D. *et al.*, 2005) that release from hair cell afferent fibers, including IHCs, and involves multivesicular release (Figure 10). Coordinated transmitter release provides a large safety factor and facilitates high temporal resolution. From studies on amphibian, chick, and mammalian auditory hair cells there is a large releasable pool of transmitter, its release is linearly proportional to the presynaptic calcium current, and the rate-limiting step seems to be release rather than refilling of the vesicles, with a critical role of vesicle-trafficking for the dense core bodies adjacent to the presynaptic membrane (Fuchs, P. A. *et al.*, 2003; Fuchs, P. A., 2005; Khimich, D. *et al.*, 2005). Ribbon synapses are specialized for fast synaptic transmission and their physiological properties that have so far been described will enable them to respond in the millisecond timescale (Parsons, T. D. and Sterling, P., 2003). The properties of the ribbon synapse would appear to optimize temporal resolution for transmitter release. At present we do not have a clear understanding of the factors that optimize temporal resolution and the brief interspike intervals in the postsynaptic afferent terminal. The major limitation to temporal resolution appears, however, to be largely presynaptic because electrically driven phase-locking in the cat auditory nerve, which bypasses the synapse, reveals that spike-generation is not the limiting factor (Dynes, S. B. C. and Delgutte, B., 1992) (Figure 13).

3.20.5.5.3 The problem with owls

If we accept that the limiting factor in phase-locking cut-off is a result of the hair-cell membrane time constant, then the time constants of the hair-cells at a particular frequency position in the cochlea would appear to be longer in rodents than those of cats, squirrel monkeys, pigeons, and blackbirds, which in turn are longer than those of owls. Given the two octave spread in phase-locking cut-off amongst these species the resistive or capacitive components in the hair cell membrane would have to change by about 4 times which would be an extremely large variation in the properties of the membrane. One further observation from phase-locking data from the guinea-pig cochlea is consistent with a variation in hair-cell properties. As a consequence of the increasing asymmetry of the IHC receptor potential with increasing frequency, phase-locking should

result in minimum instantaneous discharge rates below spontaneous rate for low frequency (below 1 kHz; Russell, I. J. and Sellick, P. M., 1983), but only down to spontaneous rate for high frequencies (above 1 kHz, see Figures 12 and 13). This phenomenon has been observed in guinea-pig data and it is clearly present in the cat data of Johnson D. H. (1980) . If the differing phase-locking cut-off frequencies are a result of the hair-cell membrane properties, we would expect the transition between minima below or above spontaneous rate to be species-dependent. For guinea-pigs, the transition is near 1.5 kHz whereas in a single fiber from cat (Johnson, D. H., 1980) it appears to be above 2 kHz, and from a single auditory nerve fiber in the owl (Köppl, C., 1997) it appears to be at least 7 kHz (Figure 13).

Phase-locking in cochlear nerve fibers responses is a consequence of two transfer functions (1) the mechanical to electrical transfer which results in the declining AC/DC ratio and (2) the transfer function of the hair-cell synapse. The sensitivity of the synaptic transfer function could be the key to phase-locking at high frequencies in the owl cochlea. If the sensitivity of the synaptic transfer function and the basal discharge rate of transmitter release were both higher in birds than in mammals, then a given magnitude of the AC receptor potential would modulate transmitter release to a greater depth from avian compared with mammalian hair cells. Correspondingly, avian afferent fibers would have higher phase-locking cut-off frequencies. While there are no apparent differences in the basal discharge rates of auditory nerve fibers in rodents and cats (3–25 spikes s^{-1} in guinea-pig, Palmer, A. R. and Russell, I. J. 1986), spontaneous discharge rate in the auditory fibers of owls is higher and up to 150 spikes s^{-1} (Köppl, C., 1997). Importantly, by comparison with mammalian auditory fibers, all auditory fibers in the bird cochlear nerves are spontaneously active. The basis for the high resting discharge rate in bird auditory fibers is not yet known. Appropriate experiments have yet to be conducted to ascertain if factors including hair-bundle biasing, increased resting calcium conductance, and postsynaptic mechanisms are responsible for the high resting discharge rates of avian auditory nerve fibers.

3.20.5.6 Dynamic Range

The combination of amplification of the BM vibrations at low levels and compression at high levels enables IHCs to signal responses over the entire dynamic range of the cochlea. The solution to coding this enormous dynamic range within the more limited scope of the spike-rate code of the auditory nerve fibers appears to be range fractionation. Extensive measurements of auditory nerve fibers in guinea-pigs led Winter I. M. *et al.* (1990) to divide the fibers into three categories. High spontaneous rate fibers display activity in the absence of any stimulus, have a low acoustic threshold, and a steep rate-intensity function at CF that almost completely saturates within 20–30 dB of the threshold. The rate-intensity functions at CF of medium spontaneous rate fibers are more sloping over their entire dynamic range. Low spontaneous rate fibers have almost no spontaneous activity, have high thresholds, and display a rate-intensity function at CF with a shallow slope. These different shapes are thought to reflect the linear and compressive regions of BM response (Yates, G. K. *et al.*, 1990). Accordingly, as demonstrated by Zagaesky M. *et al.* (1994) the synaptic transfer characteristics or hair cell receptor potential–spike rate functions must be quite different for each of the three different categories of fibers (Figure 14). A current goal is to understand the presynaptic and postsynaptic mechanisms that are the bases for these differences.

3.20.6 Outer Hair Cell Receptor Potentials

The tallest rows of stereocilia of the OHCs in the mammalian cochlea are attached by their tips to the TM and thus mechanically link the TM and BM (Figure 1). As a consequence of their strategic location in the cochlear partition, OHCs play an essential role in the frequency tuning and sensitivity of the cochlea. Following selective damage to the OHCs, the electrophysiological and mechanical responses of the cochlea to acoustic stimulation become insensitive, linear, and broadly tuned (Dallos, P., 1992; Robles, L. and Ruggero, M. A., 2001). OHCs have a bi-directional, interactive role in sensory transduction in the cochlea (Weiss, T. F., 1982; Davis, H., 1983) by both responding to vibrations of, and feeding forces back to, the cochlear partition that is the source of the cochlea's frequency tuning and sensitivity. It might be anticipated that the effectiveness of the proposed feedback depends on the mechanical properties of the BM, TM, and on the gain and phase of the feedback process.

The negative deflection near the beginning of each panel is a 5 mV calibration pulse. (b) The average rate level data for two cells with CFs ~18 kHz to a stimulus frequency of 525 Hz. (c) The broken curve is the growth function of an IHC with a CF ~18 kHz IHC. (b) The neural data and associated functions from figure 4 plotted as a function of the DC receptor potential. From figures 1 and 4 of Zagaeski, M., Cody, A. R., Russell, I. J., and Mountain, D. C. 1994 Transfer characteristic of the inner hair cell synapse, steady state analysis. J. Acoust. Soc. Am. 95, 3430–3434.

3.20.6.1 Phase and Magnitude of Outer Hair Cell and Inner Hair Cell Receptor Potentials as Indicators of Electromechanical Feedback

If the OHCs operate in a true electromotor feedback loop, then they will contribute to their own responses and hence to the mechanical responses of the cochlear partition. The net mechanical response of the cochlear partition, that is, the radial shear displacement between the TM and BM, is detected by the IHCs (Davis, H., 1965) and reflected in the IHC receptor potentials (Russell, I. J. and Sellick, P. M., 1978) and in the firing pattern of the auditory nerve fibers (Kiang, N., 1965). OHCs might be expected to make a significant contribution to the mechanical properties of the cochlear partition at low and moderate levels of the acoustic stimulus that is within the most sensitive region of the OHC transducer function (Cody, A.R. and Russell, I. J., 1987; Russell, I. J. and Kössl, M., 1992a). For tone levels within this range, the magnitude of the AC response of the OHC receptor potential might provide a measure of the feedback contributed by the OHCs to the mechanics of the cochlear partition and the phase of the AC response relative to that of the passive mechanics of the BM indicates the sign of the feedback. For high levels of the acoustic stimulus, the OHC transducer is saturated and the mechanical responses of the BM and the voltage responses of the OHCs are governed by the passive mechanical properties of the BM (Patuzzi, R. B. *et al.*, 1989; Zwislocki, J. J., 1990).

The frequency and level dependence of the phase relationships of OHC and IHC AC receptor potentials (Dallos, P., 1986; Dallos, P. and Cheatham, M. A., 1989; Cheatham, M. A. and Dallos, P., 2001; Kössl, M. and Russell, I. J., 1992), BM vibrations (Robles, L. and Ruggero, M. A., 2001; Legan, P. K. *et al.*, 2000; 2005), and phase-locking of spike discharges in the auditory nerve (Anderson, D. J. *et al.*, 1971) are all similar for frequencies around the CF. Thus, as Anderson D. J. *et al.* (1971) were the first to show, for frequencies below the CF, the response phase increasingly lagged with increasing level and above the CF, the phase of the response increasingly led with increasing level. For levels below ~60 dB SPL, the phase at CF of OHC AC receptor potentials is level independent. In sensitive *in vivo* recordings from the basal turn of the cochlea, the appearance of compression (reduction in slope) in the OHC

AC and IHC DC level functions with increasing stimulus level, is associated with a phase lead of the OHC AC response, which asymptote at about 90° (Figure 15). A feedback model of amplification in the cochlea can provide a causal relationship between the magnitude and phase of the OHC responses at the CF.

3.20.6.2 The Phase and Magnitude of Outer Hair Cell Receptor Potential and the Positive Feedback Model

Mountain D. C. *et al.* (1983) proposed a model of cochlear amplification in which OHCs contribute negative feedback that reverses through a frequency-

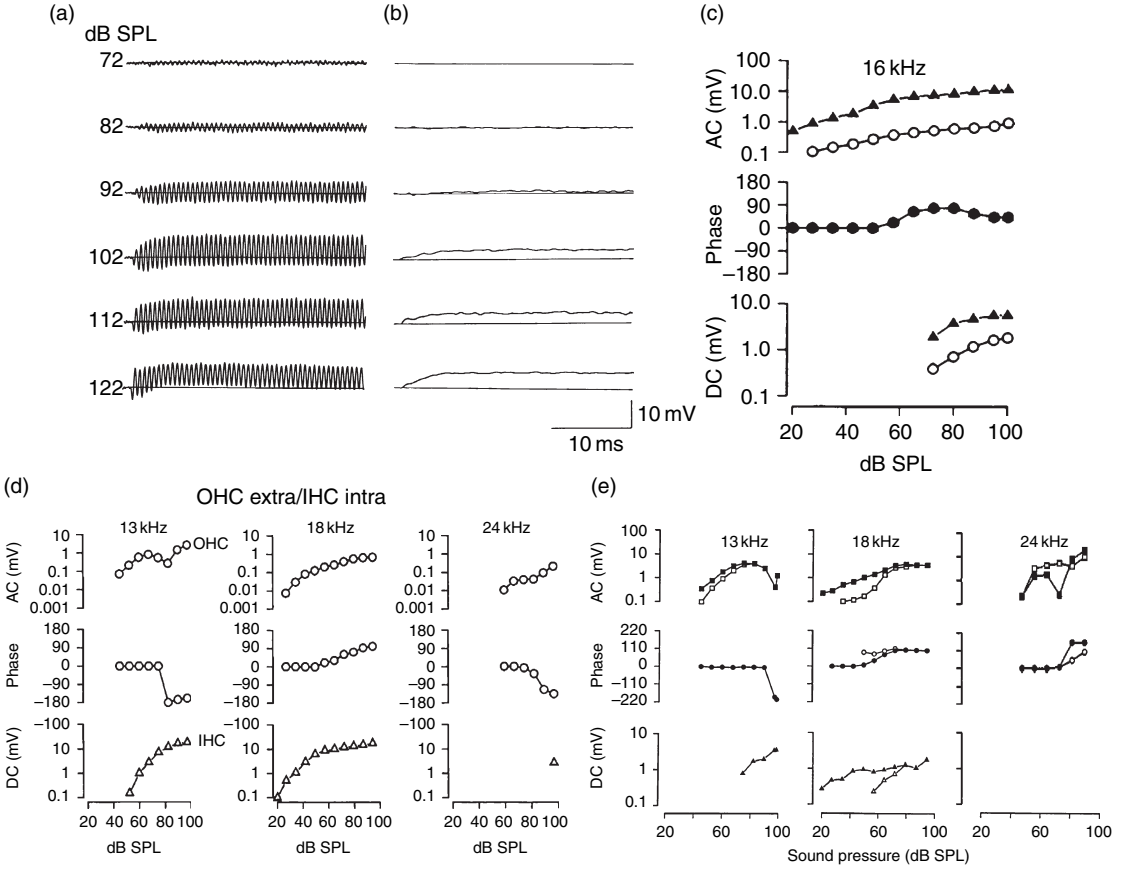

Figure 15 Receptor potential magnitudes and phase as functions of level and frequency. The OHC DC receptor potential appears when the AC potential begins to saturate, and the AC phase begins to change. (a) Receptor potentials recorded from a basal turn OHC CF ~18 kHz in response to a 3 kHz tone. (b) The same data but low-pass filtered at 1 kHz. (c) Tone-evoked voltage responses as functions of level (and at the frequencies shown) recorded intracellularly (solid triangles) and extracellularly (open circles) from an OHC. In each panel, the magnitude of the AC response (upper curves), the phase of the AC response (middle curves), and the amplitude of the DC receptor potential (lower curves) are plotted as a function of tone level. Resting potential of OHC, −70 mV, detection threshold at CF (16 kHz), 20 dB SPL. The magnitudes of the responses are root mean square (RMS) values, positive values of phase indicate leads, and the data have been compensated for recording system and membrane time constants of 3.5 and 1.1 kHz, respectively. (d) Magnitude and phase of AC responses recorded extracellularly from an OHC (open circles), and the amplitude of DC responses recorded intracellularly from an adjacent IHC (CF 18 kHz) (open triangles) as functions of level at the frequencies indicated. The magnitudes of the extracellular AC responses are corrected for the low-pass filtering of the recording electrode (corner frequency, 3 kHz). (e) Magnitude, phase, and DC response/level functions based on extracellular recordings close to an IHC at the frequencies indicated. The magnitude of the AC response is corrected by 6 dB/octave from 4 kHz to compensate for the low-pass filtering due to the recording system. (a, b) From figure 5 of Cody, A. R. and Russell, I. J. 1987. The responses of hair cells in the basal turn of the guinea-pig cochlea to tones. J. Physiol. Lond. 383, 551–569. (c, d) From figure 2 of Kössl, M. and Russell, I. J. 1992. The phase and magnitude of hair cell-receptor potentials and frequency tuning in the guinea-pig cochlea. J. Neurosci. 12, 1575–1586. (e) From figure 11 of Russell, I. J. and Kössl, M. 1992b. Modulation of hair cell voltage responses to tones by low-frequency biasing of the basilar membrane in the guinea pig cochlea. J. Neurosci. 12, 1587–l601.

dependent phase delay to positive feedback at the CF. That is, electromotor feedback from the OHCs opposes BM displacement at frequencies away from the CF, but augments BM velocity at the CF. This mechanism, through which fine-tuning of the phase of OHC feedback controls the gain of feedback, can also account for cochlear compression. If the magnitude of the OHC AC receptor potentials indicates the strength of the feedback, and their phase indicates the timing, then the phase of the feedback must be close to optimal at low stimulus levels. Presumably it is not optimal when the AC and DC level functions begin to compress, and in fact may be the cause of this compression as the vectorial strength of the feedback declines to a point where it begins to oppose rather than augment the swing of the BM. This model of compression of the electromechanical responses of the cochlea differs from the model of compression reviewed by Cooper N. P. (2003) where compression is defined by saturation of the OHC transducer function.

The proposal that OHC feedback can exert a frequency- and level-dependent negative gain on cochlea responses is supported by the findings of Kössl M. and Vater M (2000) findings that the resonance of the echo-response region of the moustached bat cochlea is enhanced following Amikacin ototoxicity. Amikacin selectively damaged the first row of the OHCs in the basal turn of the cochlea, leading Kössl and Vater to suggest that the resulting augmented resonance of the echolocation region of the cochlear partition that is largely attributable to the TM, and which is normally poised close to instability (Kössl, M. and Russell, I. J., 1995; Russell, I. J. and Kössl, M., 1999), is normally controlled through negative feedback. At the apical end of the cochlea, removal of the active attenuation/negative gain observed in BM responses above BF (Zinn, C. *et al*., 2000) could also result in hypersensitive tuning-curve tails when cochlear function is compromised.

3.20.6.3 Outer Hair Cell Excitation and the Parallel Resonance Model

Similar observations of hypersensitivity in the tuning-curve tails of neural, electrical, and mechanical responses of other cochlear regions may also be accounted for by this mechanism, although they have also been reproduced in a model by Zwislocki J. J. (1986). His model (reviewed in Zwislocki, J. J., 2002) is centered on the notion that elastically and hydromechanically coupled cochlear structures are likely to form a complex resonator. Consequently one can expect quite complex, frequency-dependent relative movements between these structures, particularly between the TM and the RL, which provides excitation of the cochlear hair cells. Some time ago Allen J. B. (1980) and Zwislocki J. J. (1980) postulated that this complex system possesses at least two resonant frequencies for each tonotopic place along the cochlea, one provided by the BM and the other by a parallel resonator formed by the TM mass and its elastic attachments to the spiral limbus and the OHC stereocilia. At the frequency of the parallel resonance, the TM moves in phase with the RL, thus resulting in a reduction in shear displacement between these structures and, as a consequence, a reduction in IHC and neural excitation. The reduction is greatest at the frequency of the parallel resonator. The same mechanism acts to reduce hair cell excitation throughout the frequency range of the low-frequency tails of cochlear response tuning curves According to this model, Zwislocki J. J. (1986) postulated that a reduction in the forces generated by the OHCs would reduce the radial motion of the TM, thereby sensitizing the low-frequency tail of tuning curves, as was first observed by Liberman M. C. and Dodds L. (1984) in neural tuning curves recorded from cochleae following acoustic trauma (Robertson, D. *et al*., 1980) and/or salicylate and ototoxicity (Murugasu, E. and Russell, I. J., 1995).

3.20.6.4 The Phase of Outer Hair Cell Excitation: A Balance between the Tectorial Membranes Radial Stiffness and Rotational Stiffness of Outer Hair Cell Stereocilia

At frequencies about one-half an octave below CF and again between one-third and one-half octave above CF, slight increases in the level of tones presented at moderate-to-high sound levels can cause the phase of the OHC AC response to jump by 180°. The phase transitions are associated with magnitude minima or notches in the fundamental AC response/level functions (Figures 15(c)–15(e)). It is suggested that these 180° phase jumps are not related to the feedback process associated with frequency tuning because they survive desensitization and loss of frequency tuning in the cochlea. These phase jumps are, furthermore, critically poised and close to instability so that biasing of the BM toward or away from the scala media can flip the phase from one state to the other (Figure 15(e) and see Russell, I. J. and Kössl, M., 1992b). These observations are in accordance with the results of similar measurements made on the gerbil cochlea by Zwislocki J. J. (1988; 1990). Phase jumps and notches have been

observed in the fundamental magnitude functions of IHCs but not OHCs in the apical turns of the guinea-pig cochlea (Dallos, P. and Cheatham, M. A., 1989; Cheatham, M. A. and Dallos, P., 2001), and magnitude minima and phase jumps have been observed in BM mechanics (Patuzzi, R. *et al.*, 1984). The 180° phase jumps may indicate that the direction of BM displacement associated with OHC excitation has become reversed. OHCs are excited by displacement of the hair bundle toward the tallest row (Russell, I. J. *et al.*, 1986a), and according to the Zwislocki J. J. (1986) mechanical model of the cochlear partition, this can be achieved by displacements of the BM toward either the scala vestibuli or the scala tympani, depending on the relative magnitude of the movements of the TM and RL. A change in the relationship, for example, between the rotational stiffness of OHC hair bundles and the radial stiffness of the TM, possibly as a consequence of a level-dependent change in the mechanical impedance of elements within the cochlear partition, could reverse the direction of excitation as proposed by Zwislocki J. J. (1986; 1988) and Mountain D. C. and Cody A. R. (1999). For example, the rotational stiffness of OHC hair bundles is reduced following intense mechanical stimulation (Saunders, D. C. and Flock, A., 1986).

3.20.6.5 Hair Cell Isoresponse Tuning Curves: Comparison with Mechanical and Neural Tuning Curves

In experiments where successive recordings were made from adjacent IHCs and OHCs tuned to the same frequency without a measurable change in cochlear sensitivity between and following the recordings, isoresponse tuning curves were found to share similar characteristics in the tip region (Dallos, P., 1985), and indeed with mechanical tuning curves measured from the same frequency region, but from another cochlea (Figure 16(a) and Russell, I. J. *et al.*, 1995). These findings were confirmed and extended when Narayan S. S. *et al.* (1998) compared BM and neural tuning curves measured from the same cochlea (Figure 16(b)). They also concluded that the tuning curves were almost

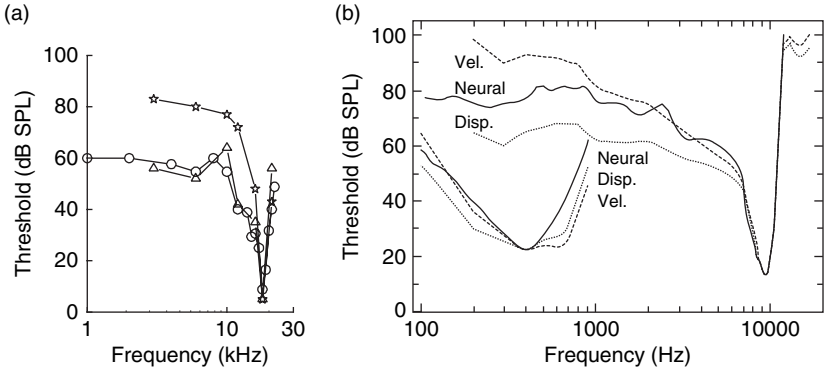

Figure 16 Hair cell, neural, and BM tuning curves compared. (a) Frequency tuning curves measured intracellularly from an IHC and OHC in the 18 kHz region of the same cochlea and isoresponse measurements of the displacement of the 18 kHz region of the BM of a different cochlea. The criteria for the isoresponse tuning curves were 0.5 mV (OHC, AC, △), 0.8 mV (IHC, DC, ○), 0.35 nm (BM, displacement ★). The resting potentials of the IHC and OHC were −45 and −65 mV respectively. The OHC AC responses are corrected for the low-pass filtering of the recording system (3.5 kHz) and OHC membrane filter (1 kHz). (b) Frequency tuning in cochlear vibrations and auditory nerve fibers in chinchilla. Curves at right: a frequency-threshold tuning curve for an auditory-nerve fiber (solid line) is compared with isoresponse curves for a BM site with identical CF (9.5 kHz) recorded in the same ear (244). At the fiber's CF threshold (13 dB SPL), BM vibrations had a peak displacement of 2.7 nm or, equivalently, 164 mm s^{-1}. These values were used to plot BM isodisplacement and isovelocity tuning curves (dotted and dashed lines, respectively). (A better mechanical/neural match was obtained by high-pass filtering the BM displacement curve at a rate of 3.8 dB/octave (not shown).) Curves at left: isodisplacement and isovelocity tuning curves (1 nm and 2.5 mm s^{-1}, respectively; dotted and dashed lines) for TM vibrations recorded at an apical cochlear site (299) are compared with a neural tuning curve (solid line), the average of recordings from many auditory-nerve fibers (Temchin, A. N., Rich, N. C., and Ruggero, M. A., unpublished observations). (a) From figure 3 of Russell, I. J., Kössl, M., and Murugasu, E. 1995. A Comparison between Tone-Evoked Voltage Responses of Hair Cells and Basilar Membrane Displacements Recorded in the Basal Turn of the Guinea Pig Cochlea. In: Advances in Hearing Research (*eds*. G. A. Manley,G.M. Klump, C. Köppl, H. Fastl, and H. Oeckinghaus), pp. 125–135. World Scientific. (b) From figure 18 of Robles, L. and Ruggero, M. A. 2001. Mechanics of the mammalian cochlea. Physiol. Rev. 81, 1305–1352.

identical in the tip region. When measured from the basal turn of the cochlea, the tuning curves of IHCs and nerve fibers are almost identical and differ from BM displacement (not velocity, Sellick, P. M. *et al.*, 1982; Narayan, S. S. *et al.*, 1998) and OHC tuning curves (which are also almost identical) in that the low-frequency tails of the tuning curves are 15–20 dB less sensitive. The similarity between neural and IHC tuning curves may indicate that synaptic transmission across the IHC afferent synapse is effectively frequency-independent, at least for frequencies above a few kilohertz. The 15–20 dB differences in the low-frequency tails of IHC and OHC tuning curves may be due to differences in the mechanical coupling between IHCs and OHCs with the TM (Dallos, P. *et al.*, 1972; Sellick, P. M. and Russell, I. J., 1980).

3.20.6.6 Factors Influencing Amplification along the Length of the Basilar Membrane

Amplification varies enormously along the length of the cochlea being about 1000-fold or more in the basal, high-frequency region of the cochlea, but little more than unity at the extreme low-frequency apex of the cochlea (Robles, L. and Ruggero, M. A., 2001; Sellick, P. M. *et al.*, 2006). What are the characteristics of the OHC's electrical responses to sound that vary down the length of the cochlea?

When recorded *in vivo* with sharp electrodes, the amplitudes of OHC receptor potentials do not appear to vary systematically down the length of the cochlea. OHC receptor potentials in response to low-frequency tones, at frequencies within the electrical time constants of the OHCs and recording systems, are similar and can exceed 30 mV in amplitude, irrespective of whether they are recorded in the apex or the base of the guinea-pig cochlea (Dallos, P., 1985; 1986; Russell, I. J. and Kössl, M., 1992b). The endocochlear potential does not vary substantially down the length of the guinea-pig cochlea being about +80 mV and neither does the resting-membrane potentials of the OHCs, being around −70 mV (Dallos, P. *et al.*, 1982; Dallos, P., 1986; Russell, I. J. and Sellick, P. M., 1983; Russell, I. J. *et al.*, 1986b). Intracellular *in vivo* recordings from hair cells are technically challenging and receptor potential magnitudes probably depend more on the quality and leakiness of the intracellular recording than on cochlear location. A systematic dependence of transducer currents and receptor potentials on cochlear location has, however, been shown from whole cell patch recordings made *in situ* in a gerbil hemicochlea preparation. He D. Z. Z. *et al.* (2004) , discovered that the transducer conductances of high-frequency basal OHCs were almost threefold greater in magnitude than those of the low-frequency apical OHCs, as indeed were the receptor currents when the OHCs were voltage-clamped at −70 mV (Figure 17). He D. Z. Z. *et al.* (2004) speculated that this variation could be a natural consequence of the increased number of stereocilia in the hair bundles of basal OHCs. They also proposed that the variation could be due to a gradation in the unitary conductance of the transducer channels, which for example in the turtle cochlea, ranges between 80 and 160 ps. Thus one basis for the vast difference in gain between the apical and basal region of the cochlea might be the differences in the size of the receptor current. Indeed, subsequent to the He D. Z. Z. *et al.* (2004) findings, Beurg, M. *et al.* (2006) found the single OHC channel conductance to vary with position along the length of the BM increasing from 145 ps in the apical coil to 210 ps in more basal locations.

An additional factor that might vary down the length of the cochlea is the sensitivity of the OHCs to BM displacement. In terms of linear displacement of the hair bundle, basal hair cells are more sensitive by a factor of six than apical hair cells. This is likely to be due to two factors, the larger transducer conductance of basal hair cells, mentioned earlier, and lever advantage between BM displacement and rotation of the hair bundle. From calculations based on the organ of Corti geometry and a kinematic study of the gerbil hemicochlea, Dallos P. (2003) proposed that the ratios of cilia angle and BM displacement for basal and apical OHCs are 20° and 10° μm^{-1}, respectively. The estimated angular sensitivity for basal and apical OHCs was 17.9 nS per degree and 2.9 nS per degree, which is ratio of about 6. He D. Z. Z. *et al.* (2004) estimated angular displacements and cilia ranges for OHCs between 10% and 90% activation of the transducer conductance from which they obtained 2.1° for the base and 1.9° for the apex. According these estimates by He D. Z. Z. *et al.* (2004) the physiological range of ciliary rotation remains constant throughout the cochlea, although it is unclear if these estimates take into account the huge differences in the magnitude of BM displacement at threshold between the apex and base of the cochlea (Robles, L. and Ruggero, M. A., 2001).

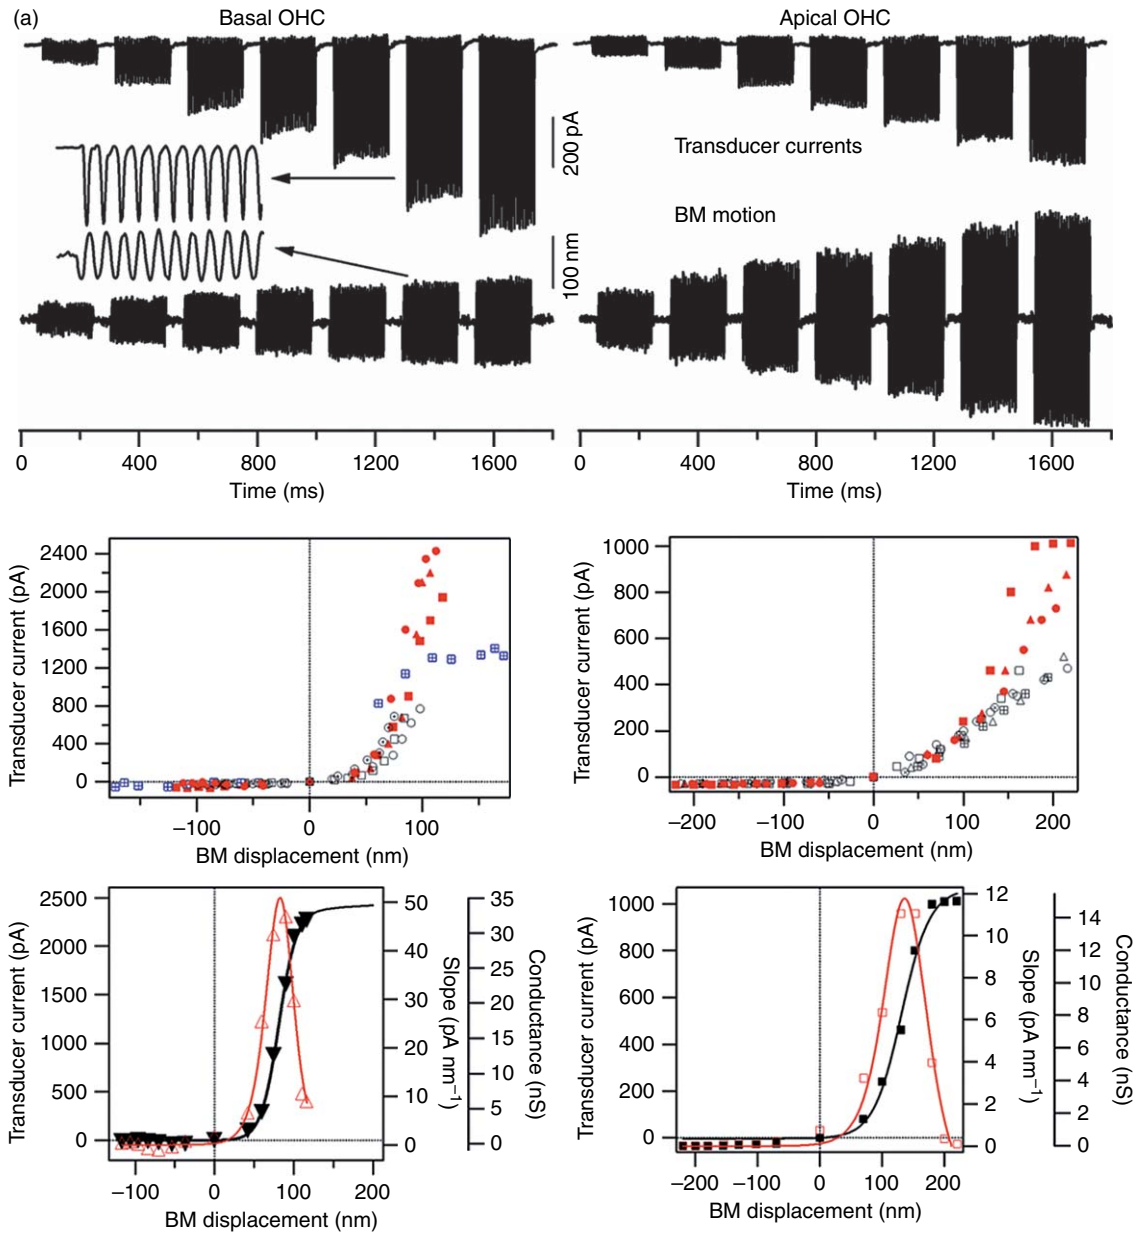

Figure 17 OHC transducer currents evoked by BM vibration. (a, b) Tight-seal recordings were made from two OHCs in the basal and apical turns at a holding potential of 270 mV. As shown on an expanded timescale in the insert, upward movement represents the BM moving toward the scala media, which evoked an increase in inward current (plotted downward in panels (a) and (b)). (c, d) Steady-state transducer current plotted as a function of BM displacement for eight basal (c) and eight apical (d) OHCs. Increase in inward current is plotted upward. Responses showing the most commonly observed behavior are plotted with black open symbols. Some of our best cells (filled red symbols) showed larger responses and intimate saturation. One fully saturated basal-turn cell, having small response and broad dynamic range, is also shown for comparison (blue symbols). (e, f) Transducer current, transducer conductance, and slope of the current function plotted for one good basal (e) and apical cell (f). The current plots are fitted with second-order Boltzmann functions, which are shown including the extrapolated saturation region (filled symbols). Slope functions (open symbols) are fitted with the derivatives of the second-order Boltzmann functions. From figure 2 of He, D. Z. Z., Jia, S., and Dallos, P. 2004. Mechanoelectrical transduction of adult outer hair cells studied in a gerbil hemicochlea. Nature 429, 766–770.

3.20.6.7 Operating Point of the Outer Hair Cell Receptor Potential

Receptor potentials and transducer currents have been recorded from isolated preparations of the neonatal mouse cochlea (Russell, I. J. *et al.*, 1986a; 1986b; Kros, C. J. *et al.*, 1992; Gèlèoc, G. S. G. *et al.*, 1997). In these preparations and in the gerbil hemicochlea, receptor potentials and transducer currents recorded from OHCs have a strong depolarizing asymmetry (Figure 3). The OHCs operate around the point of greatest inflexion such that at rest only about 6–10% of the transducer conductance is open and thus resemble the receptor potentials and currents recorded from hair cells in the frog sacculus, where the hair bundles are freestanding after the otolithic membrane is removed (Hudspeth, A. J. and Corey, D. P., 1977). The point of maximum sensitivity of the transducer conductance is not at this location on the OHC transfer function, but at the location of the maximum slope of the transfer function (Figures 18 and 19 and Russell, I. J. and Kössl, M., 1992a). From recordings made *in vivo*, OHCs in the basal turn of the guinea-pig cochlea operate close to this location (Russell, I. J. and Sellick, P. M., 1983; Russell, I. J. *et al.*, 1986b). There is however, a gradient of operating points down the length of the BM, such that OHCs in the upper coils of the cochlea produce largely depolarizing receptor potentials to tones of moderate levels (Dallos, P., 1985; 1986). The dependence of the operating point on the presence of the TM, as was demonstrated in measurements from mice where the TM is detached from the organ of Corti and the OHC receptor potentials, resemble those of other freestanding hair cells (Figure 20 and Legan, P. K. *et al.*, 2000).

3.20.6.8 Control of the Outer Hair Cell Transducer-Operating Point

The OHC transducer-operating point is not fixed but is a dynamic phenomenon and depends on the frequency, level, and duration of the tone and the frequency location of the OHC within the cochlea. Frequency and level-dependent changes in the symmetry of the receptor potential have been observed for middle and apical turn OHC in the guinea-pig cochlea (Dallos, P., 1985; 1986). In basal turn OHCs, the receptor potentials in response to tones several octaves in frequency below the CF, are symmetrical to tone-levels that generate responses close to the noise floor of the recording (~60 dB SPL). The receptor potentials become

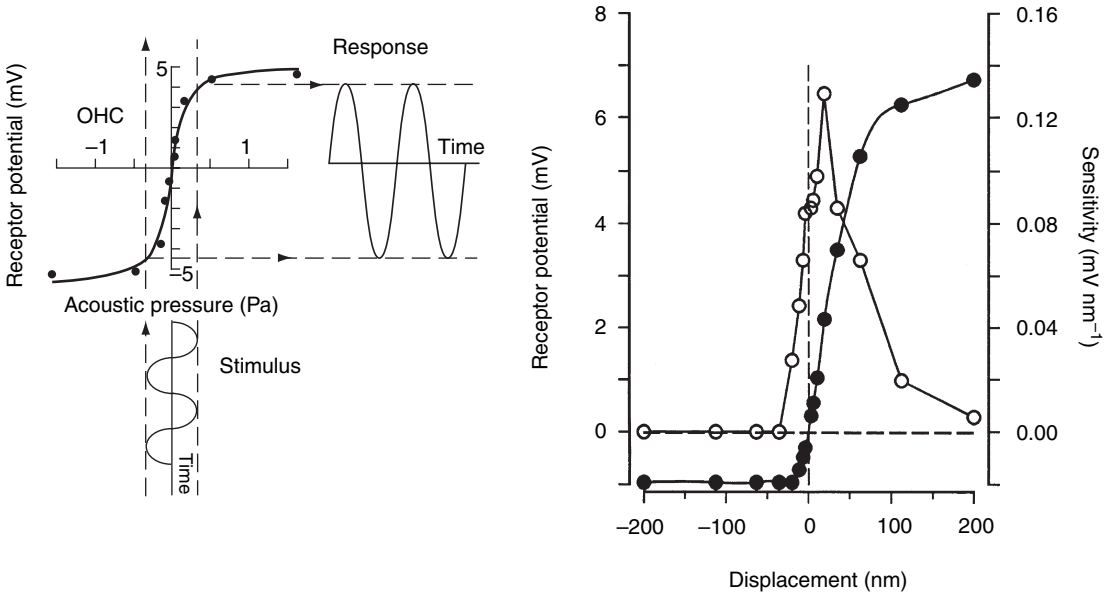

Figure 18 OHCs in the basal turn operate about the steep, most sensitive region of their input–output curve. (a) OHC transfer function based on *in vivo* data from Russell *et al.* 1986b. (b) OHC transfer function based on *in vivo* data (filled circles). The open circles plot the slope, and hence the sensitivity, of this relationship. (b) From Russell, I. J. and Kössl M. 1992a. Sensory transduction and frequency-selectivity in the basal turn of the guinea-pig cochlea. Philos. Trans. R. Soc. Lond. Ser. B. 336, 317–324.

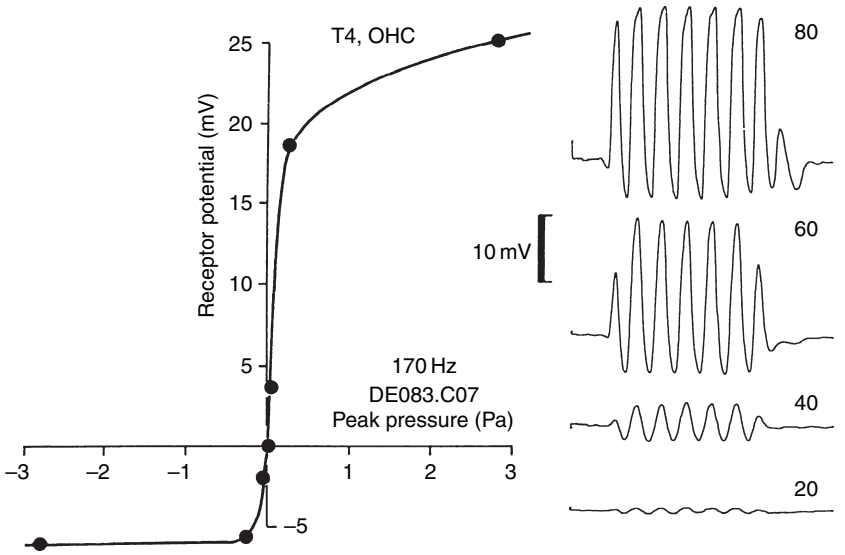

Figure 19 Peak AC response magnitude as a function of peak sound level for a fourth turn OHC. Stimulus frequency is near the BF of the cell. Corresponding waveforms are shown on the right side of the figure. From figure 9 of Dallos, P. 1986. Neurobiology of cochlear inner and outer hair cells, intracellular recordings. Hear. Res. 22, 185–198.

hyperpolarizing when the stimulus tone exceeds ~70 dB SPL, symmetrical at ~90 dB SPL, and depolarizing for levels above this. These level- and frequency-dependent changes in the OHC operating point are a natural consequence of the nonlinear properties of the OHC transducer function (Lukashkin, A. N. and Russell, I. J., 1998) and may also be due to interaction between the hair bundles and the TM rather than through interaction with the BM, at least for levels below 90 dB SPL. Level-dependent tonic displacements of the BM in the basal, high-frequency region of the cochlea have not been reported for levels below 90 dB SPL (Russell, I. J. *et al.*, 1986b).

3.20.6.9 Displacement of the Outer Hair Cell Transducer-Operating Point and Gain Optimization

From CM measurements to low-frequency tones following intense pure tone stimulation, Patuzzi R. *et al.* (1989) proposed that electromechanical feedback to the cochlea is directly related to the amplitude of the transducer current (Patuzzi, R. *et al.*, 1989). It has also been suggested that feedback is maximized when the DC component of the OHC receptor potential is minimized (Russell, I. J. *et al.*, 1986b; Russell, I. J. and Kössl, M., 1992a). In this feedback circuit, it was proposed that the error signal is the DC component of the OHC voltage response, which controls the OHC voltage-dependent motility and hence adjusts the length of the OHC to restore the radial displacement of the hair bundle and OHC transducer-operating point to optimum sensitivity. Changes in the membrane potential, length, and membrane tension of the OHCs alter voltage-dependent motility (Santos Sacchi, J., 2003) and hence should influence feedback gain. Thus, any displacement of the operating point of the OHC transducer away from the position of maximum sensitivity would reduce the gain of the transducer and hence the feedback.

There is evidence to support this proposal from *in vivo* intracellular current injection of OHCs in the basal turn of the cochlea that fast voltage-sensitive motility is responsible for automatic control of the OHC transducer-operating point. When single OHCs in the basal turn of the guinea-pig cochlea are injected *in vivo* through an intracellular electrode with current while the cochlea is stimulated with low-frequency tones, the OHC receptor potentials are decreased in amplitude and made more symmetrical with negative current (Figures 21(a) and 21(b)), which hyperpolarizes OHCs and presumably causes them to elongate. The OHCs receptor potentials are increased in amplitude and made positively asymmetrical with positive current, which depolarizes OHCs and presumably causes them to shorten (Russell, I. J. and Kössl, M., 1991). Current injection into IHCs does not

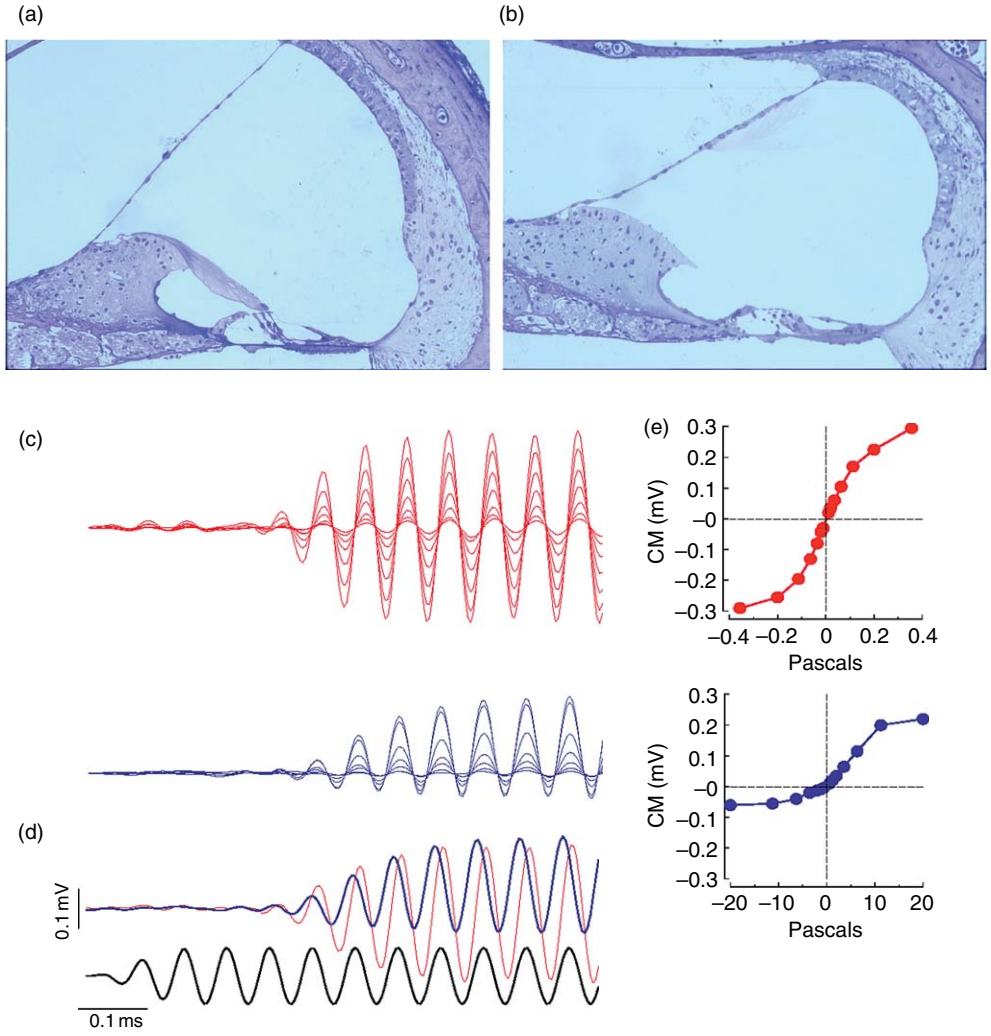

Figure 20 OHC operating point is controlled by the TM. Tolludin blue stained sections of the cochlea of (a) wild type mice and (b) *Tecta*Δ*ENT/DENT* mouse with detached TM. J., Lukashkin, A. N., Verhoeven, K., Van Camp, G., Russell, I. J., and Richardson, G. P. 2000. A targeted deletion in α-tectorin reveals the tectorial membrane is required for the gain and timing of cochlear feedback. Neuron 28, 273–285.

strongly alter the waveforms of their low-frequency receptor potentials but they do alter the magnitudes in predictable ways (Figure 21(c)). This mechanism has also been proposed as a means for controlling the gain of OHCs following activation of the efferent medial olivocochlear system (Murugasu, E. and Russell, I. J., 1996).

Low-frequency biasing of the BM alters the gain of electromechanical feedback to the cochlear partition (Patuzzi, R. and Sellick, P. M. 1984; Russell, I. J. and Kössl, M. 1992b; Cheatham, M. A. and Dallos, P., 1994; 1997). The AC components of receptor potentials recorded from OHCs to tones close to their CF were suppressed when the BM was displaced away from its resting position toward either scala tympani or scala vestibuli by low-frequency (100 Hz) biasing tones (Russell, I. J. and Kössl, M., 1992b). Russell, I. J. and Kössl, M. suggested that this suppression was due to a reduction in feedback from the OHCs as a consequence of a reduction in the gain of mechanoelectrical transduction due to displacement of the OHC transducer operating. The AC responses were

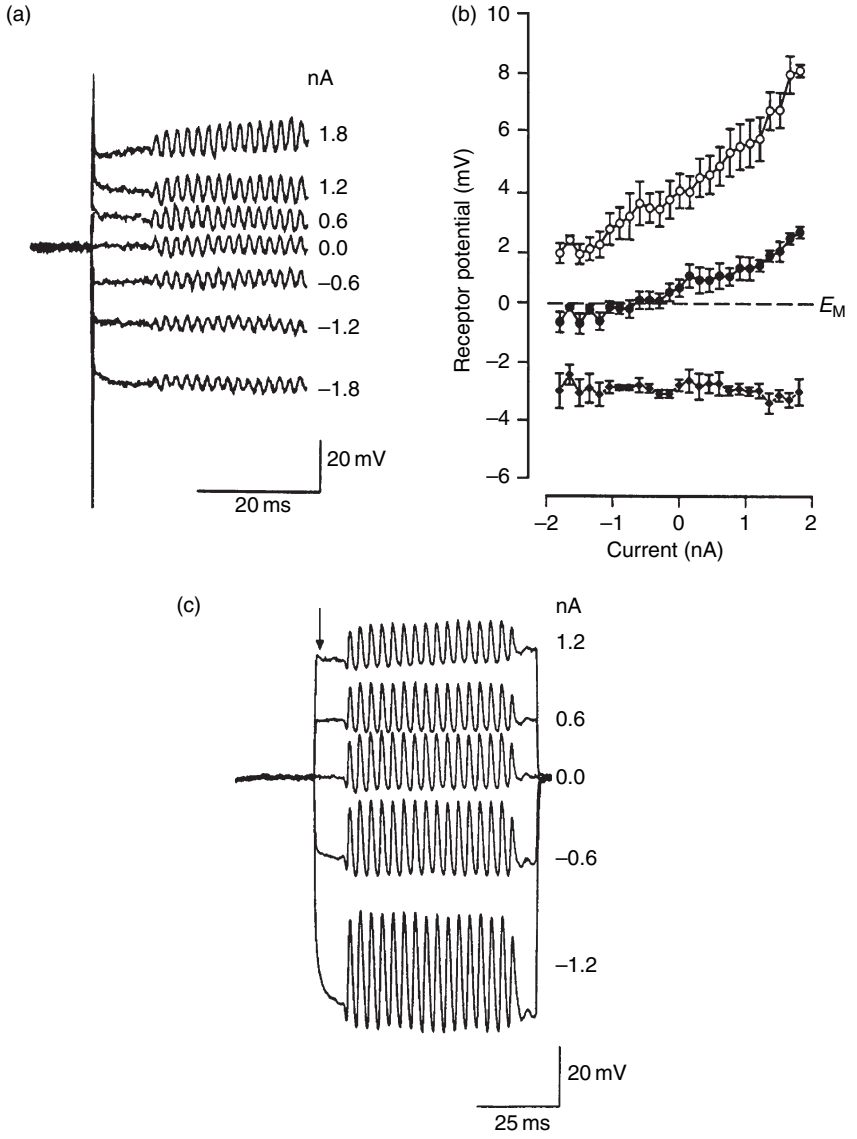

Figure 21 Intracellular current injection changes the symmetry of OHC but not IHC receptor potentials. (a) Receptor potentials recorded from an OHC when stimulated with 600 Hz tones at 80 dB SPL and during current injection. (b) Peak positive (○), peak negative (●) and DC (■) receptor potentials of the OHC and those of a further four OHCs in two other preparations as a function of injected current. EM (dashed line), indicates the membrane potential. Each point represents the mean and standard deviation of the pooled data. (b) Responses of an IHC to positive and negative current injection, voltage responses to 300 Hz tones at 90 dB SPL. From figures 1 and 6 of Russell, I. J. and Kössl M. 1991. The voltage responses of hair-cells in the basal turn of the guinea-pig cochlea. J. Physiol. Lond. 435, 493–511.

attenuated maximally at low levels of the near-CF tone when the combined levels of the biasing and CF tones are below the level of saturation of the transducer conductance (Patuzzi, R. *et al.*, 1989). Suppression was reduced when the high-frequency AC response became saturated and almost disappeared with the appearance of the OHC DC response to the HF tone.

Suppression of IHC responses to tones at frequencies around CF by low-frequency biasing of the cochlear partition (Patuzzi, R. and Sellick, P. M., 1984; Russell, I. J. and Kössl, M., 1992b) is due, therefore, primarily to changes in the mechanical input to the OHCs that are brought about as a consequence of the suppression of the OHC AC responses by the biasing tone. Displacement of the OHC operating

point can have profound effects on the gain of cochlear amplification as revealed in the responses of the IHCs. Indeed, in insensitive preparations, biasing of the cochlear partition can enhance IHC responses, presumably through shifting the operating point of the OHC transducer to a more sensitive position (Figure 22).

Zou Y. *et al.* (2006) re-examined these earlier proposals and findings and plotted the operating point movement of OHC stereociliary bundles derived from an analysis of the second and third harmonics of the CM waveform (Frank, G. and Kössl, M., 1997; Kirk, D. L. and Patuzzi, R., 1997; Bian, L. *et al.*, 2002; Lukashkin, A. N. and Russell, I. J., 2005). On the basis of this analysis, Zou Y. *et al.* (2006) inferred that the operating point was shifted by sound or by applied force to the otic capsule. Through the application of perfusion hydraulic pressure, force, and loud sound Zou Y. *et al.* (2006) , revealed that maintenance of the operating point was a dynamic process. They argued that fast prestin-based motility could be the basis for restoring the operating point, but the long-time constants of recovery they observed might be a consequence of slower potential mechanisms such as depolarization of the OHCs from potassium accumulation in the spaces of Nuel (Johnstone, B. M. *et al.*, 1989), calcium and ATP-dependent motility (Zenner, H. P., 1986), and mechanical processes such as cell turgor or stiffness (Santos-Sacchi, J., 2003).

3.20.6.10 Temporary Threshold Shift in Cochlear Sensitivity and Changes in the Operating Point of the Outer Hair Cell Transducer

Experiments based on direct measurements of IHC and OHC responses to intense tones challenge the view that cochlear desensitization is associated with saturation of the transducer conductance and may also provide insight into the way in which OHC responses can shape the frequency responses and dynamic ranges of IHCs at frequencies at and away from the CF. In experiments where responses to intense tones were measured from adjacent IHCs and OHCs in the basal high-frequency region of the same cochlea, Cody A. R. and Russell I. J. (1995) showed that although the hair bundles of IHCs are freestanding, IHC transducer functions can be controlled by the OHCs, even at frequencies several octaves below the CF. When the mammalian cochlea is exposed to brief (<200 ms) loud tones (~110 dB SPL), both IHCs and OHCs develop rapid and sustained AC voltage

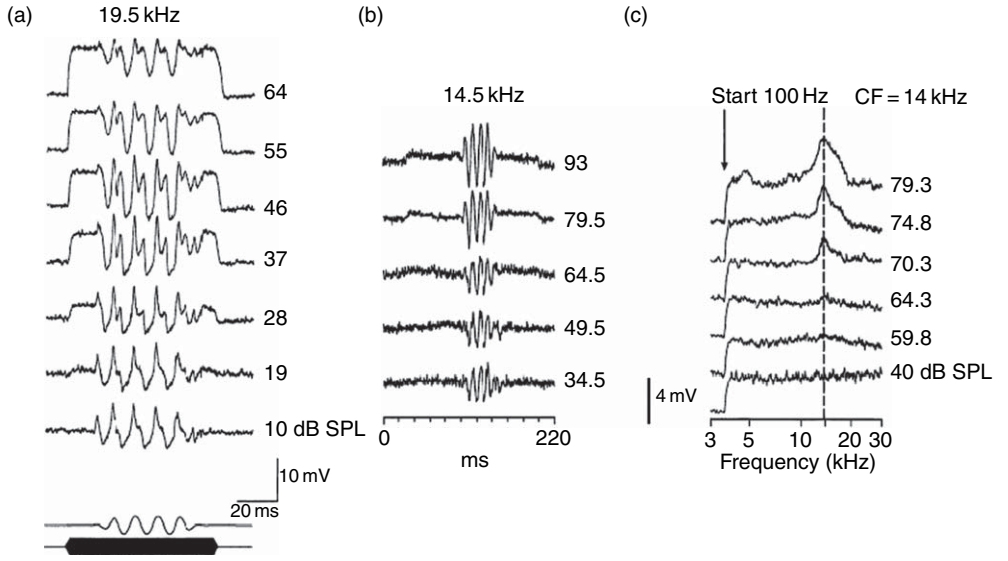

Figure 22 Intracellular voltage responses of an IHC to a combination of 80 dB SPL, 100 Hz tones and a tone at 19.5 kHz (CF) at the levels shown to the right. The waveform of the 100 Hz tone and the envelope of the HF tone are shown at the bottom. Resting membrane potential, −40 mV. The voltage responses are low-pass filtered at 3 kHz. Intracellular responses of an insensitive IHC to combined 100 Hz, 80 dB SPL tones and HF tones. (a) Voltage responses of the IHC to 100 Hz and 14 kHz tones at the levels shown to the right. (b) Magnitude of the 100 Hz response measured with the lock-in amplifiers as a function of the frequency and level of the HF tone when it is swept from 3 to 30 kHz. Resting membrane potential, −40 mV. From Russell, I. J. and Kössl, M. 1992b. Modulation of hair cell voltage responses to tones by low-frequency biasing of the basilar membrane in the guinea pig cochlea. J. Neurosci. 12, 1587–l601.

responses. The DC component of the IHC receptor potential is developed concurrently with the AC potential and it is sustained, with little variation, for the duration of the acoustic stimulus. In contrast, the DC component of the OHC receptor potential develops at a significantly slower rate and continues to grow as long as the acoustic stimulus is present. At tone-offset, the membrane potential returns over periods of 10s of ms to the resting-membrane potential (Figure 23). For longer stimuli (up to 8 s) at frequencies about half an octave below the CF, the OHC response is simply an extension of the response to the short tone burst. That is, the AC component of the voltage response remains constant and the DC component continues to grow with time. The magnitude of the IHC AC component also remains constant throughout the tone burst, but the DC component declines by more than 50% for an 8 s exposure. During long-term exposures, the complex time constants for the growth of the OHC DC and the decay of the IHC DC are very similar, although opposite in sign, indicating a common origin. Presentations of a low-frequency tone, either during the intense tone or immediately afterwards, reveals a basis for the decline in the IHC DC response; the receptor potentials become more symmetrical. Consequently the DC component declines relative to the magnitude of the AC component, which remains constant for the duration of the intense tone, although the harmonic distortion of the waveform decreases, which might be expected if the IHCs are operating in a more linear region of the transfer function. What, therefore, cause the depolarization and shift in symmetry of the OHC receptor potentials and how might this influence the waveforms of the IHC responses?

Depolarzsation of OHCs and other cellular elements of the organ of Corti during intense tones is believed to be due to the accumulation of potassium ions in the extracellular fluid-filled spaces of Nuel that surround the basolateral membranes of the OHCs (Cody, A. R. and Russell, I. J., 1985; 1987; Johnstone, B. M. *et al.*, 1989; Oesterle, E. C. and Dallos, P., 1986; 1990). The subsequent depolarization of the OHCs would cause the OHCs to shorten, thereby altering the way IHCs are stimulated so that their hair bundles become biased to a more linear region of the transducer transfer function. Other possible factors, such as intracellular accumulation of calcium in the stereocilia and change in stiffness of the OHC hair bundles (and indeed in the IHC

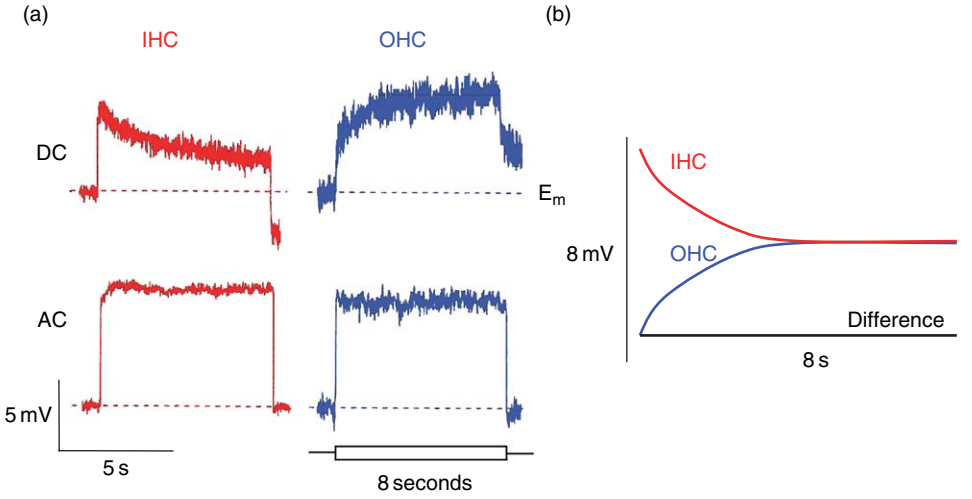

Figure 23 DC receptor potentials recorded from IHCs and OHCs in response to intense tones are mirror opposites of each other. (a) Intracellular receptor potentials generated by an IHC and an OHC) in response to a 12.5 kHz continuous tone at a level of 105 dB sound pressure level. The upper half of the figure represents the DC component of the receptor potential and the lower half represents the magnitude of the AC or phasic component measured using a lock-in amplifier (time constant 10 ms). In this case the fundamental component (12.5 kHz) is shown. Em. is the intracellular resting membrane potential (IHC, −32 mV; OHC, −78 mV). The period of the 8-second tone is indicated at the bottom of the figure. (b) An expanded and averaged plot of the data shown in the left hand figure. IHC (red trace) DC voltage response to a tone delivered for 8 seconds (12.5 kHz, 105 dB SPL). OHC (blue trace) DC voltage response to an 8-second continuous tone (12.5 kHz, 105 dB SPL). Difference (black trace) in membrane potential change for the IHC and OHC (OHC-IHC) depicted in (a). Redrawn and recalculated from original data used in Cody and Russell, 1995.

bundles), could also contribute to the forces exerted on the TM that might reduce the subtectorial space and hence bias the freestanding bundles of the IHCs.

3.20.6.11 Control of the Outer Hair Cell Operating Point and Shaping of the Outer Hair Cell Receptor Potential Tuning Curve

The level- and frequency-dependent behavior of the operating point of the OHC transducer function could also potentially contribute to shaping the high- and low-frequency shoulders of the tuning curve, although experiments directed at this question remain to be performed. There are hints from hair cell responses to low-frequency biasing tones that the OHC operating point does have a role in shaping the tuning curve from earlier experiments. For example, IHC DC/level functions and OHC AC/level functions share similar characteristics for frequencies around CF (Figures 15(c) and 15(d)). OHC and IHC AC and IHC DC receptor potentials are also similarly suppressed by BM displacements both toward and away from scala tympani (Figure 15(e)). At frequencies more than about 3 kHz below CF, however, the OHC AC/level functions are more sensitive than the IHC DC level functions (Figures 15(d) and 15(e)). At these frequencies, the OHC AC responses are suppressed by biasing tones at levels below those that elicit IHC DC responses (Figure 15(e)). At threshold levels for the IHC DC responses (~70 dB SPL), the suppressive influence of the 100 Hz tone on the OHC AC response (and hence on the IHC DC response) is no longer apparent. Thus control of the operating point of the OHC transducer can control the gain of cochlear amplification at frequencies away from the CF, and thereby shape the tip of the tuning curve.

3.20.7 Exploiting Compound Potentials to Understand Cochlear Function and Dysfunction

There is renewed interest in the measurement of extracellular receptor potentials from the cochlea and the extent to which they can reveal information about the transducer current and the way this is shaped by the basolateral conductances of hair cells. This approach is important because the technique is technically less demanding and far less invasive than the making of electrophysiological measurements from hair cells or sections of the organ of Corti isolated from the cochlea, where there have to be serious concerns about the extent to which these measurements reflect normal, *in vivo* function in the cochlea. The ability to probe the molecular basis of sensory transduction and amplification in the mammalian cochlea using techniques that are relatively noninvasive and easy to conduct is of great potential value in experiments using transgenic mice where proteins associated with the transduction apparatus and the dominant extracellular matrices have been modified. There have been several interesting attempts to explore the possibility of using the CM and SP to derive cochlear transducer functions largely from Patuzzi's laboratory in Perth (Patuzzi, R. and Moleirinho, A., 1998; Patuzzi, R. and O'Beirne, G. A., 1999) using custom-built electronics and software. Patuzzi and his colleagues estimated the transfer curve relating instantaneous sound pressure in the ear canal to instantaneous receptor current through the OHCs in the basal turn of the guinea-pig cochlea using the CM in response to 200 Hz tones. The transfer curve was approximated by a first-order Boltzmann activation curve which they analyzed automatically to continuously and swiftly derive the three parameters defining the curve. Their techniques offer a convenient method of monitoring changes in OHC mechanoelectrical transduction in the basal turn of the cochlea (Patuzzi, R. *et al.*, 1989) due to cochlear disturbances.

More recently Choi C.-H. *et al.* (2004) have constructed a cochlear transducer function from the SP recorded from the RWs of gerbils using a low-frequency bias tone. They assumed that the SP generated in the basal turn of the cochlea is due largely to the IHCs (Durrant, J. D. *et al.*, 1998). The transducer function could be fitted with a second-order Boltzmann function in line with the treatment of transducer functions constructed from electrical recordings of vestibular and cochlear hair cells (Hudspeth, A. J., 1982; Kros, C. J. *et al.*, 1992). Choi C.-H. *et al.* (2004) were conservative and did not attribute the derived transfer function specifically to IHCs. This is in part because at the 70–90 dB SPL levels of the 6 kHz and 12 kHz probe tones and a 25 Hz bias tone at 130 dB SPL they employed, OHCs in the basal turn might be expected to generate DC components in their receptor potentials, as has been shown for OHCs in the basal turn of the guinea-pig cochlea (Cody, A. R. and Russell, I. J., 1987).

The CAP is the synchronous sound-evoked activity of cochlear neurons that can be monitored by

placing an electrode on the RW. This compound neural potential has been used extensively throughout the history of cochlear electrophysiology to assess the sensitivity of the cochlea and as a criterion for determining if cochlear function has been impaired (see Dallos, P., 1973). The ability to derive masking frequency tuning curves from the CAP that closely resemble single unit threshold tuning curves (Dallos, P. and Cheatham, M. A., 1976) has been used more recently to examine frequency tuning in the cochleae of mice with deletions and mutations of the motor protein prestin (Cheatham, M. A. *et al*, 2004; 2005) and the tectorins of the TM (Legan, P. K. *et al*., 2005; Russell, I. J. *et al*., 2007).
